Abstract. The Lena River Delta, which is the largest delta in the Arctic, extends over an area of 32 000 km² and likely holds more than half of the entire soil organic carbon (SOC) mass stored in the seven major deltas in the northern permafrost regions. The geomorphic units of the Lena River Delta which were formed by true deltaic sedimentation processes are a Holocene river terrace and the active floodplains. Their mean SOC stocks for the upper 1 m of soils were estimated at 29 kg m⁻² ± 10 kg m⁻² and at 14 kg m⁻² ± 7 kg m⁻², respectively. For the depth of 1 m, the total SOC pool of the Holocene river terrace was estimated at 121 Tg ± 43 Tg, and the SOC pool of the active floodplains was estimated at 120 Tg ± 66 Tg. The mass of SOC stored within the observed seasonally thawed active layer was estimated at about 127 Tg assuming an average maximum active layer depth of 50 cm. The SOC mass which is stored in the perennially frozen ground at the increment 50–100 cm soil depth, which is currently excluded from intense biogeochemical exchange with the atmosphere, was estimated at 113 Tg. The mean nitrogen (N) stocks for the upper 1 m of soils were estimated at 1.2 kg m⁻² ± 0.4 kg m⁻² for the Holocene river terrace and at 0.9 kg m⁻² ± 0.4 kg m⁻² for the active floodplain levels, respectively. For the depth of 1 m, the total N pool of the river terrace was estimated at 4.8 Tg ± 1.5 Tg, and the total N pool of the floodplains was estimated at 7.7 Tg ± 3.6 Tg. Considering the projections for deepening of the seasonally thawed active layer up to 120 cm in the Lena River Delta region within the 21st century, these large carbon and nitrogen stocks could become increasingly available for decomposition and mineralization processes.

1 Introduction

Degradation of permafrost is affected by climate change (e.g., Grosse et al., 2011; Romanovsky et al., 2010), but also results in important feedbacks to climate change (e.g., Schuur et al., 2009; Schaefer et al., 2011). Therefore, the characterisation of permafrost-underline areas, permafrost-affected soils, and their soil organic carbon (SOC) and nitrogen (N) stocks are important for understanding interactions of the biogeochemical cycle with global climate. The area occupied by permafrost-affected soils amounts to more than 8.6 million km², which is about 27 % of all land areas north of 50° N (Jones et al., 2010). Enormous amounts of organic matter have accumulated in permafrost-affected soils during the Quaternary period (Harden et al., 1992; Smith et al., 2004; Zimov et al., 2006; Gorham et al., 2007; Schirrmeister et al., 2011). Recent estimates show that today there might be up to 496 Pg (1 Pg = 10¹⁵ g) of SOC stored within the uppermost one metre of the permafrost-affected soils (Tarnocai et al., 2009). Although the area occupied by the main arctic deltas as indicated by Walker (1998) amounts only to 77 000 km² (total area of arctic and alpine tundra: 7.4 × 10⁶ km² according to Loveland et al., 2000), their contribution to the total SOC pool within the permafrost-underline areas is high (Tarnocai et al., 2009) due to the large thickness of their deposits resulting from typical river deltaic sedimentation and accumulation processes (e.g., Schwamborn et al., 2002). Permafrost-affected soils are expected to undergo fundamental property changes due to the observed and projected climate changes (Koven et al., 2011), including higher decomposition rates of organic matter and increased
The investigation area in the Lena River Delta in northeast Siberia with the location of Samoylov Island (Map B based on Google and Geocentre Consulting 2011).

release of the greenhouse gases carbon dioxide and methane to the atmosphere (Dutta et al., 2006; Wagner et al., 2007; Khvorostyanov et al., 2008; Schuur et al., 2008, 2009; Grosse et al., 2011). Thus, permafrost-affected soils have to be considered as a globally important element of the cryosphere within the global climate system. The majority of published articles on element stocks in permafrost-affected soils focuses on the North American region. In recent years, however, some areas of the Eurasian permafrost – especially in the Russian region – have also been increasingly studied (Kolchugina et al., 1995; Matsuura and Yefremov, 1995; Chestnyck et al., 1999; Stolbovoi et al., 2006; Gundelwein et al., 2007; Hugelius and Kuhry, 2009).

Most previous studies analysed carbon pools of specific regions or components of permafrost-affected soil carbon pools (e.g., Stolbovoi, 2002; Tarnocai et al., 2003; Zimov et al., 2006; Ping et al., 2008; Bliss and Maursetter, 2010; Schirrmeister et al., 2011), resulting in the overall challenge to compare and combine the different regional assessments, including soil type/order-specific SOC pools and pools calculated over various depths. First important steps towards unification in mapping the distribution of soil types and soil carbon stocks were achieved by assembling the Soil Atlas of the Arctic (Jones et al., 2010) and a new pan-arctic estimate of SOC pools in permafrost regions (Tarnocai et al., 2009). These studies suggest that the total SOC pool of the permafrost-affected soils to 3 m depth is very high at 1024 Pg (Tarnocai et al., 2009), exceeding the carbon pools within the entire global vegetation biomass (650 Pg) or the atmosphere (750 Pg) (IPCC, 2007). However, despite this improved quantification, SOC data for the huge areas of Siberia are still scarce, uncertainties are high, and more detailed landscape-scale assessments are necessary (Tarnocai et al., 2009; Zubrzycki et al., 2012).

Here, we focus on the assessment of soil organic carbon and total nitrogen pools in the Northeast-Siberian Lena River Delta. The area that the Lena River Delta occupies amounts to 42% of the total area of all arctic deltas. Analysing the GIS-Polygons of the Northern Circumpolar Soil Carbon Database (Hugelius et al., 2013) corresponding to the spatial extent of the Lena River Delta, the SOC pool of this delta for the depth of 1 m can be estimated to be around 670 Tg carbon. While the Lena River Delta consists of various geomorphic units, including some of non-deltaic origin (Schwamborn et al., 2002), our study concentrates on the element stocks of soils in areas of Holocene deltaic sedimentation, in particular the Holocene river terrace and the active floodplains. The first goal of the study was a detailed quantification of the SOC as well as the N stocks of the different soil units on Samoylov Island, located in the southern-central Lena River Delta. Of special interest in this region were the rarely investigated currently perennially frozen layers from 50 cm up to 100 cm depth. Samoylov Island is composed of two geomorphic parts that are regarded to be representative for the Holocene river terrace and the active floodplains within the Lena River Delta, respectively. The second goal was to upscale the results from Samoylov Island across the correspondent soil-covered areas of the Holocene river terrace and the floodplains within the Lena River Delta using remote-sensing data (Landsat-7 ETM+ and WorldView-1) and to estimate the SOC and the total N pools for these areas.

2 Study area

Our study site is located on Samoylov Island (72° 22′ N, 126° 30′ E) situated at one of the main Lena River channels, the Ol’enyokskaya Channel in the southern central part of the Lena River Delta, about 180 km south of the coast of the Arctic Ocean (Fig. 1). At around 32 000 km² (Are et al., 2000), the Lena River Delta is the largest arctic delta. It is located in north-eastern Siberia, where the Lena River cuts through the Verkhoyansk Mountains and discharges into the Laptev Sea, a part of the Arctic Ocean.

The Lena River Delta consists of three main geomorphic terrace-like units and the modern floodplain levels (Grigoriev, 1993; Schwamborn et al., 2002). Only the youngest river terrace and the modern floodplains are of Holocene deltaic origin, while the second and third terrace-like units are largely of pre-Holocene age and have a different composition and genesis (Schwamborn et al., 2002). Within this study, only the two Holocene deltaic units were sampled.

Samoylov Island is part of this Holocene delta and consists of two major geomorphic parts (Akhmadeeva et al., 1999) (Fig. 1a) which vary in sedimentary composition as well as contents of organic matter in the soils. The western part of Samoylov Island is represented by a modern floodplain up to 5 m above sea level (a.s.l.) which is flooded annually in spring. The eastern part of the island consists of an elevated (10–16 m a.s.l.) river terrace of Late Holocene age (Pavlova and Dorozhkina, 1999). Between these two units, there is a distinct and sharp step of about 5 m (Kutzbach, 2006). The river terrace is flooded only during extreme flooding events.

(Schwamborn et al., 2002). This Holocene river terrace is characterised by ice wedge polygons with wet sedge tundra vegetation. Polygonal structures imply micro-scale variability in the topography with polygonal centres and polygonal rims. The rims generally are elevated and characterised by pronounced cryoturbation. The centres can be of different quality depending of the development stage (French, 2007). Low-centred polygons have depressed centres with high water saturation during the summer months. High-centred polygons are characterised by elevated centres and are drier compared to the centres of low-centred polygons. The soils of Samoylov Island are Orthels and Turbels (Pfeiffer et al., 2000, 2002; Boike et al., 2012) according to the US Soil Taxonomy (Soil Survey Staff, 2010). The Soil Complex Glacic Aquiturbel/Typic Historthel dominates the Holocene river terrace (Fig. 2, Table 1) (Fiedler et al., 2004; Kutzbach et al., 2004) and is characterised by ice wedge polygons. The sandy active floodplain is dominated by Psammentic Aquorthels (Fig. 2, Table 1) (Pfeiffer et al., 2002). Furthermore, there are Psammorthels and Fibristsels with different subgroups distributed over the island (Sanders et al., 2010). Mean maximum active layer thickness at the river terrace currently is about 50 cm in August (Boike et al., 2012). Thaw depths are larger on the floodplain.

These two geomorphic units found on Samoylov Island are also widespread in the Lena River Delta and dominate the northern, eastern and central delta. In the western delta, Ulrich et al. (2009) studied the surface-spectral and soil characteristics of geomorphic units and also separated a Holocene river terrace and the active floodplains from the second and third main geomorphic terrace. Soil characteristics and active layer depths in their study are similar to those found on Samoylov Island. Morgenstern et al. (2008) estimated the combined area of the Holocene river terrace and the active floodplain levels at 55 % of the Lena River Delta area.

The investigation area is dominated by an arctic-subarctic climate with continental influence and is characterised by low temperatures and low precipitation. The mean annual air temperature, measured at the climate reference site in Tiksi (71°41’N, 128°42’E), which is located about 110 km south-east from Samoylov Island, was −13.5 °C, and the mean annual precipitation was 323 mm during the 30 yr period 1961–1990 (Roshydromet, 2011). The average temperature of the warmest month (August) was 7.1 °C, whereas the coldest month is January with −32.4 °C (Roshydromet, 2011) indicating an extreme seasonal temperature amplitude typical for continental polar regions. Data derived from the meteorological station on Samoylov Island indicated a mean annual air temperature of −12.5 °C from 1998–2011 and a low mean...
annual rainfall (liquid precipitation) of around 125 mm for years 1999–2011 (Boike et al., 2012).

The region is underlain by deep continuous permafrost of 400–600 m thickness (Grigoriev, 1960; Yershov et al., 1991).

3 Methods

3.1 Soil coring and sampling

For this study, a portable permafrost auger set was used to obtain shallow undisturbed cores of frozen ground material. The set consisted of an engine power head (STIHL BT 121, Andreas Stihl AG & Co. KG) and a Snow-Ice-Permafrost-Research-Establishment (SIPRE) coring auger (Jon’s Machine Shop, Fairbanks, Alaska) originally designed by the Cold Region Research and Engineering Laboratory (CRREL). We collected 37 frozen cores of minimum 1 m length in April and May 2011 (Zubrzycki, 2012). Four cores were excluded from further analysis because they did not match our quality requirements. These requirements were that the length of the undisturbed sample should be ≥ 1 m and that the sample site was not a water-filled polygon. The remaining frozen cores were subsampled immediately in the field laboratory due to the logistical limits for sample weight. We ing frozen cores were subsampled immediately in the field

The set consisted of an engine power head (STIHL BT 121, Andreas Stihl AG & Co. KG) and a Snow-Ice-Permafrost-Research-Establishment (SIPRE) coring auger (Jon’s Machine Shop, Fairbanks, Alaska) originally designed by the Cold Region Research and Engineering Laboratory (CRREL). We collected 37 frozen cores of minimum 1 m length in April and May 2011 (Zubrzycki, 2012). Four cores were excluded from further analysis because they did not match our quality requirements. These requirements were that the length of the undisturbed sample should be ≥ 1 m and that the sample site was not a water-filled polygon. The remaining frozen cores were subsampled immediately in the field laboratory due to the logistical limits for sample weight. We sliced six \((i = 1, 2, \ldots, 6)\) cylindrical samples (each with a volume of approximately 92 cm\(^3\)) of each of the cores from the following depths: 0–2 cm \((i = 1)\), 8–10 cm \((i = 2)\), 28–30 cm \((i = 3)\), 48–50 cm \((i = 4)\), 73–75 cm \((i = 5)\), and 98–100 cm \((i = 6)\). These depths were selected to get detailed information of the depth distribution of the SOC and N pools within the first metre of ground. The depth of 2 cm and 10 cm were selected to detect differences in SOC and N pools of the youngest soil accumulation. The depth of 30 cm was selected for comparison with literature citing this special depth (e.g., Stolbovoi, 2002; Hugelius et al., 2010; Zubrzycki et al., 2012) as well as the depth of 100 cm (e.g., Post et al., 1982; Ping et al., 2008; Tarnocai et al., 2009; Bliss and Maursetter, 2010). 50 cm was the mean maximum active layer thickness in August and was selected to clearly differentiate between the active and perennially frozen layer. The depth of 75 cm was selected to have additional information for the perennially frozen layer between the depths of 50 cm and 100 cm.

3.2 Soil analyses

The gravimetric contents of organic carbon \(c_{OC}\) and total N \(c_{N}\) were analysed with an element analyser based on high temperature combustion and subsequent gas analysis (Vario MAX CNS, Elementar Analyseysteme GmbH, Germany) using oven-dried (12 h at 105°C) and ground samples (ISO 10694, 1995). The bulk density \(\rho_d\) was calculated as the ratio of the dry mass of an undisturbed soil sample and the volume of a cylindrical sample of a core with a height of 20 mm and the diameter of 76 mm. There were no coarse fragments > 2 mm in any of the undisturbed soil samples.

The volumetric ice contents were calculated using the determined gravimetric ice contents (drying soils at 65°C for 2 days and measuring the frozen-fresh sample mass before and the dry sample mass after drying) and the specific ice density of 0.9167 g cm\(^{-3}\) at 0°C.

3.3 Organic carbon and total nitrogen stock calculations

The volumetric contents of SOC \(\rho_{OC}\) and total N \(\rho_{N}\) (both in kg m\(^{-3}\)) of the 2-cm soil layers were calculated as

\[
\rho_{OC} = c_{OC} \cdot \rho_d \tag{1}
\]

and

\[
\rho_{N} = c_{N} \cdot \rho_d \tag{2}
\]

where \(c_{OC}\) and \(c_{N}\) are the gravimetric contents of organic carbon and total N, and \(\rho_d\) is the bulk density. For the estimation of the SOC and total N stocks over specific soil depths, volumetric contents of SOC and total N of the non-sampled soil layers between the 2-cm soil layers that were sampled and analysed were estimated by linear interpolation in 1-cm intervals. Stocks of SOC \(S_{OC}(h_r)\) and total N \(S_{N}(h_r)\) over different reference depths \(h_r\) were then calculated by integrating the volumetric contents of organic carbon and total N over soil depth \(h\) from the soil surface \((0\ cm)\) to the respective reference depths \(h_r\) as:

\[
S_{OC}(h_r) = \int_{0cm}^{h_r} \rho_{OC} \cdot dh \tag{3}
\]

and

\[
S_{N}(h_r) = \int_{0cm}^{h_r} \rho_{N} \cdot dh \tag{4}
\]

where the following reference depths \(h_r\) were chosen: 2 cm, 10 cm, 30 cm, 50 cm, 75 cm, 100 cm.

3.4 Synthesis of existing soil information

In addition to investigating the general SOC stocks of Samoylov Island based on our new core data and a characterisation of morphological units on this island, we also synthesized existing soil data from Samoylov Island mapped during previous expeditions (Pfeiffer et al., 2000, 2002). Prior to reanalysing the Samoylov soil data we updated the existing soil map (Pfeiffer et al., 2000; Sanders et al., 2010; Zubrzycki et al., 2012) for Samoylov Island with the extent of the island shape in August 2010 (Fig. 1). This was necessary due to the dynamic geomorphic processes occurring within the central Lena River Delta. For example, we observed high erosion rates in the south eastern and pronounced accumulations rates in the western part of the island.
3.5 Organic carbon and total nitrogen pool calculations

For the calculation of the SOC and N pools for the two geomorphic units investigated on Samoylov Island, upscaling of the $S_{OC}$ and $S_N$ stocks of all investigated reference depths was performed by multiplying the means of $S_{OC}$ and $S_N$ of all those depths by the estimated areas of the two geomorphic units, the Holocene river terrace and the active floodplain levels, respectively.

3.6 Satellite data and image processing

3.6.1 Image data and processing

A Landsat image mosaic covering more than 98% of the delta was used to determine the extent of the Holocene river terrace and the active floodplains. The mosaic was generated from three Landsat-7 ETM+ satellite images taken during the summer on 27 July 2000 (path 131, row 8 and 9) and on 26 July 2001 (path 135, row 8). A detailed description of the image processing, atmospheric corrections, image co-referencing and mosaicking is provided by Schneider et al. (2009). The final mosaic has a spatial resolution of 30 m, encompasses the multispectral Landsat-7 bands 1–5 and 7, and has a horizontal accuracy of about 50 m.

The areas of the sand-rich Arga Complex belonging to the 2nd main geomorphic unit in the Lena River Delta, and the Yedoma islands of the 3rd main geomorphic unit were not considered in our study of the Holocene and active delta portions. Therefore, we removed these areas by clipping with a mask based on geographic information system layers provided by Morgenstern et al. (2008) and Morgenstern et al. (2011), who delineated the extent of the Lena River Delta terraces manually from the same Landsat image mosaic under inclusion of cryostratigraphic and geologic field knowledge. In addition, we masked the sandy barrier islands offshore the western delta and the mountainous mainland areas along the southern delta boundary.

For accuracy assessment of our classification of the Holocene river terrace and the active floodplains, we used multiple WorldView-1 images (panchromatic band, 0.5 m ground resolution) from three different delta portions as independent high-resolution datasets from which we visually interpreted land unit type. The images were acquired during the snow-free seasons of 2009 (26 September and 7 August) and 2011 (11 June). The images have a geolocation accuracy better than the Landsat pixel size. For all processing steps we used ArcGIS 10 (ESRI).

3.6.2 Supervised classification

As a result of prior knowledge of the investigated area based on personal field experience, a supervised classification technique was selected. Based on our field knowledge, we were able to set up training areas for the classification and assign them to a class category. Specifically, we created ten training sample areas per target geomorphic unit in the Lena River Delta. Based on general geomorphic classifications of the Lena River Delta by Grigoriev (1993), the target units for our image classification were (1) the Holocene river terrace, (2) the active floodplains, and (3) the water bodies, all of which are spectrally largely dissimilar. We then performed a Maximum Likelihood Classification with the training sample areas using all available multispectral bands 1–5 and 7 of the Landsat-7 ETM+ images.

3.6.3 Post-classification imagery processing

A post-classification generalization of the results was performed in ArcGIS. After grouping connected pixels of the same class into regions we merged isolated pixels surrounded entirely by pixels of a different class with that class. Lastly we re-assigned class identity for pixels in regions consisting of less than four pixels to identify and assign the most appropriate class for such pixels from its nearest neighbours (ArcGIS Resource Center, 2012). We next excluded all water bodies > 3600 m² (4 Landsat pixels) from the satellite imagery of the Lena River Delta for later upscaling over soil-covered areas only. Additionally, we corrected the extent of the Holocene river terrace’s soil-covered area reducing it by the percentage of small water ponds and troughs (14%) detected by high-resolution aerial photography for Samoylov Island (Sachs et al., 2010).

3.6.4 Accuracy assessment of the classifications

Within the footprint of the WorldView-1 images that overlapped with delta portions, we randomly selected 150 points in the delta regions covered by our three main classes (water, Holocene terrace, active floodplain) (Fig. 3). Both Holocene terrace and active floodplains are clearly differentiated in their characteristics in these high resolution images. While the active floodplain areas do not have any relief and any ice wedge polygonal structures, the Holocene river terrace shows well developed ice wedge polygons. For all points we first visually interpreted the dominant land unit within a 10 m circular buffer from WorldView-1 data and then extracted the class from our Landsat classification for direct comparison. Data points were then cross-tabulated and classification accuracy for all investigated classes calculated according to Congalton (1991).

3.7 Statistics

Descriptive statistics, correlation analyses as well as analyses of variances (response variables: $c_{OC}$ and $c_N$; samples: river terrace, floodplain) for soil data were performed using the SPSS package version 16.0.1.

4 Results

4.1 Analytical results

The mean \(\rho_d\) within the floodplain soils varied among the different six investigated soil layers from 1.0 g cm\(^{-3}\) ± 0.7 g cm\(^{-3}\) to 1.5 g cm\(^{-3}\) ± 0.3 g cm\(^{-3}\) whereas the mean \(\rho_d\) of the soils sampled on the higher elevated river terrace varied between 0.2 g cm\(^{-3}\) ± 0.3 g cm\(^{-3}\) and 0.9 g cm\(^{-3}\) ± 0.5 g cm\(^{-3}\) (Table 2). The results generally showed a high scatter ranging from 0.08 g cm\(^{-3}\) to 2.37 g cm\(^{-3}\) at the floodplains and 0.02 g cm\(^{-3}\) to 2.0 g cm\(^{-3}\) at the river terrace, respectively. Within the soil profiles there was a clear increase of the mean \(\rho_d\) with depth to a point where the \(\rho_d\) reached a relatively stable value with depth. For the soils of the river terrace, this point was around 30 cm below the soil surface for an \(\rho_d\) of about 0.9 g cm\(^{-3}\). For the active floodplain levels, it was around 10 cm below the soil surface for an \(\rho_d\) of 1.5 g cm\(^{-3}\) (Table 2).

The ice contents were higher in soils of the Holocene river terrace than in soils of the active floodplain levels. The soils of the river terrace had mean volumetric ice contents of more than 65 %, the soils of the floodplains mean contents of around 35 %, respectively (Table 3). The results of the volumetric ice content determination showed in soils of the Holocene river terrace a smooth distribution with depth and values of 61 % ± 21 % to 70 % ± 19 %. Within the soils of the floodplain the values of the ice contents scattered between 27 % ± 18 % and 47 % ± 25 % (Table 3).

The gravimetric contents of organic carbon \(c_{OC}\) showed a high scatter ranging from 0.17 % to 42.46 % in the soils of the Holocene river terrace and ranging from 0.13 % to 27.71 % in the soils of the active floodplain levels (Fig. 4a, b). The highest mean \(c_{OC}\) were measured in the soil surface layers (0–2 cm) (river terrace: 21.85 % ± 10.86 %, active floodplains: 5.89 % ± 9.88 %), followed by the soil layers in the depth from 8–10 cm (river terrace: 12.77 % ± 9.60 %, active floodplains: 1.65 % ± 1.49 %). The soils of the river terrace had significantly higher \(c_{OC}\) than the soils of the active floodplains (One-way ANOVA: \(p = 0.002–0.047\)).

The gravimetric contents of total N \(c_N\) were significantly higher (One-way ANOVA: \(p = 0.001–0.049\)) in the soils of the river terrace than in the soils of the active floodplains (Fig. 5). There was a distinct decrease of the contents...
Table 4. Results of the C/N ratio determination for all six investigated soil depths and both geomorphic units, the Holocene river terrace and the active floodplain levels, with the mean values and the respective standard deviations as well as the minima and maxima.

with increasing depth of the soil profile within both morphological units: from 0.51 % ± 0.20 % in the surface layers to 0.21 % ± 0.15 % at a depth of 98–100 cm in the soils of the river terrace and from 0.19 % ± 0.23 % in the surface layers to 0.05 % ± 0.003 % at a depth of 98–100 cm in the soils of the active floodplain levels. The cN ranged between 0.01 % and 0.90 % in the soils of the river terrace and between 0.01 % and 0.67 % in the soils of the active floodplains, respectively.

The C/N ratios ranged between 9 and 70 and were distinctively different in the soils of the river terrace and the soils of the active floodplains and additionally varied with depth (Table 4). The mean C/N ratios in the uppermost layers were 41 ± 14 at the river terrace and 21 ± 11 at the floodplains, respectively. In the deepest investigated soil layers (98–100 cm), the C/N ratios were 21 ± 8 at the river terrace and 13 ± 2 at the floodplains, respectively.
4.2 Soil organic carbon stocks

The overall mean SOC stock estimated for a reference depth of 1 m \( S_{OC} \) (100 cm) using all selected cores \( (N = 29) \) was 25.7 kg m\(^{-2}\) ± 12.0 kg m\(^{-2}\), with a median of 24.9 kg m\(^{-2}\). The estimated \( S_{OC} \) (100 cm) had a minimum of 6.5 kg m\(^{-2}\) and a maximum of 48.6 kg m\(^{-2}\).

The SOC stock within the seasonally thawed active layer \((0–50 \text{ cm}) \) \( S_{OC} \) (50 cm) reached 13.0 kg m\(^{-2}\) ± 5.3 kg m\(^{-2}\). The perennially frozen soil layers \((50–100 \text{ cm}) \) store 49 % of the entire estimated \( S_{OC} \) (100 cm). The summed total stocks for the reference depths of 0–30 cm, 0–75 cm were: 7.7 kg m\(^{-2}\) ± 3.2 kg m\(^{-2}\) and 19.2 kg m\(^{-2}\) ± 8.5 kg m\(^{-2}\), respectively.

4.2.1 Holocene river terrace and the active floodplains

The \( S_{OC} \) (100 cm) for the soils across the investigated island showed a broad range of 42.0 kg m\(^{-2}\), indicating a high heterogeneity among the sampled cores. To get a more differentiated picture of the SOC stocks of the two geomorphic units, we separated the samples of the Holocene river terrace \((N = 22) \) and the floodplain \((N = 7) \), respectively. We found pronounced differences between the soils in these two units. Generally, distinctly higher \( S_{OC}(h_t) \) were found in the soils of the Holocene river terrace \((\text{Figs. 6, 4c, d}) \). The mean \( S_{OC} \) (100 cm) in soils of the river terrace was estimated at 29.5 kg m\(^{-2}\) ± 10.5 kg m\(^{-2}\) with a median of 27.0 kg m\(^{-2}\) (minimum 12.7 kg m\(^{-2}\), maximum 48.5 kg m\(^{-2}\)). The \( S_{OC} \) (100 cm) in soils of the active floodplains were lower with a mean of 13.6 kg m\(^{-2}\) ± 7.4 kg m\(^{-2}\) and a median of 11.6 kg m\(^{-2}\) (minimum 6.5 kg m\(^{-2}\), maximum 26.6 kg m\(^{-2}\)).

4.2.2 Polygon centres, polygon rims, and soil units

To account for pronounced small-scale spatial soil variability within the polygonal tundra of the Holocene river terrace, we analysed and compared the characteristics of cores from the polygon rims \((N = 6) \) and from the polygon centres \((N = 16) \). Additionally, separate core analyses were done on the soil subgroup level.

The estimated mean SOC stock within the surface layers \( S_{OC} \) (2 cm) was substantially higher in the polygon rims \((0.9 \text{ kg m}^{-2} ± 0.5 \text{ kg m}^{-2}) \) than for the corresponding layers in the polygon centres \((0.5 \text{ kg m}^{-2} ± 0.3 \text{ kg m}^{-2}) \). Including the soil layers down to 10 cm depth, this difference decreased \(( S_{OC} \) (10 cm) was 3.2 kg m\(^{-2}\) ± 1.5 kg m\(^{-2}\) for the rims and 2.5 kg m\(^{-2}\) ± 0.9 kg m\(^{-2}\) for the centres). The estimated mean SOC stock within 30 cm depth \( S_{OC} \) (30 cm) was slightly higher in the centres \((8.8 \text{ kg m}^{-2} ± 2.8 \text{ kg m}^{-2}) \) than at the rims \((7.5 \text{ kg m}^{-2} ± 3.1 \text{ kg m}^{-2}) \). The mean SOC stock over 1 m deep soil profiles \( S_{OC} \) (100 cm) was 33.3 kg m\(^{-2}\) ± 9.7 kg m\(^{-2}\) in the centres with a median of 34.5 kg m\(^{-2}\), whereas at the polygonal rims the mean \( S_{OC} \) (100 cm) was 19.4 kg m\(^{-2}\) ± 3.7 kg m\(^{-2}\) with a median of 19.5 kg m\(^{-2}\).

The results of the analyses on soil subgroup level indicated a large variability among the eight known soil subgroups of Samoylov Island \((\text{Fig. 7}) \). The \( S_{OC} \) (100 cm) estimates based on the one sampled core were 31.1 kg m\(^{-2}\) for the Typic Aquorthel (silty) and 45.3 kg m\(^{-2}\) for the Typic Aquiturbel/Typic Aquorthel soil complex, respectively. The results of the mean \( S_{OC} \) (100 cm) estimations for the other soil units of Samoylov Island with a higher number of sampled cores showed a high scatter \((\text{Fig. 7}) \). Minima ranged from 6.5 kg m\(^{-2}\) to 19.5 kg m\(^{-2}\), maxima ranged from 20.4 kg m\(^{-2}\) to 48.5 kg m\(^{-2}\). The mean carbon stocks of the different soils varied strongly within the soil units as well as across the depth profiles \((\text{Fig. 8}) \).

4.3 Nitrogen stocks

The \( S_N \) (100 cm) of the investigation area varied between 0.41 kg m\(^{-2}\) and 1.94 kg m\(^{-2}\). The mean N stock amounted to 1.10 kg m\(^{-2}\) ± 0.39 kg m\(^{-2}\) \((\text{Table 5}) \).
Fig. 7. A soil map of Samoylov Island as a result of long-term soil research within this area. Generated from data by Pfeiffer et al. (2000) and Pfeiffer et al. (2002) (compare Sanders et al., 2010). Soil classification according to the US Soil Taxonomy (Soil Survey Staff, 2010). Mean soil organic carbon stocks with their standard deviations for the soil units down to 100 cm depth are provided in parentheses after each soil subgroup. (ACRONYM – soil subgroup (number of soil cores)): AACC – Fluvaquentic Fibristel (2), ACBH – Psammentic Aquorthel (5), ACBD – Ruptic-Histic Aquorthel (3), Soil Complex: ABBB/ ACAF – Glacic Aquiturbel/ Typic Historthel (10), Soil Complex: ABBF/ ACBJ – Typic Aquiturbel/ Typic Aquorthel (1), ACBJ (Sandy) (22.7 ± 13.4), ACBJ (Silty) (31.1), ACGD (15.2 ± 4.6).

Regarding the two different investigated geomorphic units, the Holocene river terrace and the active floodplain levels, the mean N stocks were 1.18 kg m$^{-2}$ ± 0.36 kg m$^{-2}$ and 0.88 kg m$^{-2}$ ± 0.40 kg m$^{-2}$, respectively. The distinctly higher total N stock of the Holocene river terrace had a different vertical distribution. While the active floodplain stored about 53% of the entire estimated N stock within the seasonally thawed active layer (depth 0–50 cm), only 48% of the N stock of the river terrace was determined in the seasonally thawed active layer (Table 5). The polygon centres had higher $S_N$ (100 cm) than the polygon rims (0.96 kg m$^{-2}$ ± 0.31 kg m$^{-2}$). The rim soils stored about 57% of their $S_N$ (100 cm) within the seasonally thawed active layer, whereas only 45% were stored in this active layer at the polygon centre soils (Table 5).

Fig. 8. Soil organic carbon stocks (kg m$^{-2}$) of the soil subgroups identified on Samoylov Island according to the US Soil Taxonomy (Soil Survey Staff, 2010) for different reference depths $h_r$. (A) $h_r = 2$ cm; (B) $h_r = 10$ cm; (C) $h_r = 30$ cm; (D) $h_r = 50$ cm; (E) $h_r = 75$ cm; (F) $h_r = 100$ cm. Note different scale for y-axis on all graphs. For acronyms along x-axis see Fig. 7.

The $S_N$ (100 cm) for the soil subgroup-related analyses showed mean values between 0.85 kg m$^{-2}$ ± 0.31 kg m$^{-2}$ and 1.94 kg m$^{-2}$ for the specific soil subgroups. High $S_N$ (100 cm) was found in the two soil complexes of Aquiturbels and Historthels that dominate Samoylov Island (Table 6). Regarding the vertical distribution of the N contents, high differences emerged among the various soil subgroups. On average, 50% of the $S_N$ (100 cm) was stored within the upper 50 cm of soil indicating a homogenous distribution over soil depth. In the soil complex of Glacic Aquiturbels and Typic Historthels, only 42% was stored within this layer, whereas 63% of the $S_N$ (100 cm) was found in the upper 50 cm of the Typic Aquorthel (silty) (Table 6).

4.4 Land surface classification and upscaling

Based on the Landsat-7 ETM+ satellite image mosaic (Fig. 9a), the results of our supervised classification confirmed previously reported ratios of the water- and land-covered areas in the Lena River Delta (Fig. 9b) of approximately 31% and 69%, respectively (Schneider et al., 2009). The area covered by water bodies > 3600 m$^2$ amounted to around 10000 km$^2$. Furthermore, the results indicated that the geomorphic unit dominating the Lena River Delta are the active floodplain levels occupying about 8830 km$^2$ (Fig. 9c). This area represents approximately 40% of the soil-covered area of the Lena River Delta. The investigated Holocene river terrace (1st terrace) (Fig. 9c) occupies 4760 km$^2$ which

After correcting for the spatial coverage of small ponds in the polygonal tundra of the Holocene river terrace, the soil covered land area of the river terrace, which we used for later calculations and upscaling, amounted to 4090 km².

The results of the upscaling (Fig. 9d) reflect the near-linear increase of SOC stocks with increasing reference soil depths that was found in the analysed soil cores from Samoylov Island. The surface soil layers ranging from 0–2 cm store a total SOC mass of 2.4 Tg ± 1.5 Tg on the Holocene river terrace and 3.0 Tg ± 2.0 Tg on the active floodplain, respectively. We estimated for the reference depth of 50 cm a SOC pool of 59.9 Tg ± 18.5 Tg for the river terrace and 67.2 Tg ± 34.0 Tg for the floodplains (Table 8). This depth is approximately the average depth of the seasonally thawed active layer in the summer. The total pools of the SOC stored within a depth of 100 cm were estimated at 120.7 Tg ± 43.0 Tg on the Holocene river terrace and at 119.8 Tg ± 65.6 Tg on the active floodplains of the Lena River Delta. Roughly 47 % of the SOC mass stored within the top 100 cm of soils in the investigation area, specifically about 61 Tg at the young river terrace and 53 Tg at the floodplains, are located within the currently perennially frozen layers deeper than 50 cm.

The N stored within the top 100 cm of soils was estimated at 4.8 Tg ± 1.5 Tg for the Holocene river terrace and at 7.7 Tg ± 3.6 Tg on the active floodplains of the Lena River Delta. About 49 % of this N pool within the top 100 cm of soils was found within the currently perennially frozen layers. This proportion was 52 % on the Holocene river terrace, and 47 % on the active floodplains (Table 9).

5 Discussion

5.1 Soil organic carbon pools on the Holocene river terrace and the active floodplains

In this study, we do not consider woody debris in our estimates due to its spatially very inhomogeneous distribution and basically absent field data. However, there is certainly...

* Other includes coastal beach and a drained lake basin on the 2nd geomorphic delta terrace.

a considerable C stock in the Holocene delta area that consists entirely of wood trunks buried in soils. Our mean S\(_{OC}\) (100 cm) estimate for the soils of the Holocene river terrace amounts to 29.5 kg m\(^{-2}\) ± 10.5 kg m\(^{-2}\) and is distinctly higher than some older published estimates of mean organic carbon stocks stored in permafrost-affected tundra soils. Post et al. (1982) estimated the average SOC stock in tundra soils worldwide at 21.8 kg m\(^{-2}\). Kolchugina et al. (1995) pro-
Fig. 9. Landsat-7 ETM+ remote-sensing image mosaic of the Lena River Delta from 27 July 2000 and 26 July 2001 (A), results of land-water classification (B), results of classification into main geomorphic terraces (C), and upscaling of soil organic carbon stocks to Holocene river terrace and active floodplain levels (D).

Provided an estimate of 21.4 kg m$^{-2}$ for Russian tundra soils, whereas Matsuura and Yefremov (1995) estimated the SOC stock in Russian permafrost-affected soils to be between 11 kg m$^{-2}$ and 20 kg m$^{-2}$. Chestnyck et al. (1999) estimated the SOC stock in East European Russian tundra soil at 17.8 kg m$^{-2}$. More recent publications, however, provided higher stocks for tundra soils. Gundelwein et al. (2007) estimated the SOC stock in tundra soils of the Taymyr Peninsula at 30.7 kg m$^{-2}$. For the North American Arctic lowlands, Ping et al. (2008) reported SOC stocks of 25.9 kg m$^{-2}$. Tarnocai et al. (2009) estimated the organic carbon stocks in Turbels and Orthels of the circumpolar permafrost at 32.2 kg m$^{-2}$ and 22.6 kg m$^{-2}$, respectively. Hugelius and Kuhry (2009) estimated the stocks in northeastern European Russian tundra soils at 38.7 kg m$^{-2}$. Only Stolbovoi et al. (2006) reported a lower stock estimate of 16.6 kg m$^{-2}$ for Russian tundra soils. Ping et al. (2011) found a stock of 41 kg m$^{-2}$ in river deltas along the Alaska Beaufort Sea coastline. The estimate we provide for the Holocene river terrace (29.5 kg m$^{-2}$) lies in the range of the more recently reported estimates. The estimate for soils of the active floodplains of 13.6 kg m$^{-2}$ ± 7.4 kg m$^{-2}$ cannot readily be compared with general estimates for tundra regions. Due to their fluvial origin and ongoing episodic reworking, the soils of the Lena River Delta floodplains consist of stratified middle to fine sands and silts with layers of allochthonous organic matter as well as autochthonous peat (Boike et al., 2012). Parts of the floodplain are densely vegetated. However, generally the regular flooding events enable only sparse vegetation adjacent to the river channel. Though, our estimate is still notably higher than the mean C stock of sparse tundra (1.4 kg m$^{-2}$) in the database used by Hugelius and Kuhry (2009). Hugelius et al. (2011) reported a SOC stock for the sediments of the Rogovaya River in northeastern European Russia of 11.7 kg m$^{-2}$ which is very close to the estimate we present for the soils of the active floodplain strongly affected by active fluvial sedimentation by the Lena River.

5.2 Soil organic carbon storage in the patterned ground and the soil subgroups

Our estimates for the two characteristic microforms of the polygonal landscape, the polygon centres and polygon rims demonstrated a high micro-scale variability of the SOC stock within the investigated area. The mean $S_{OC}$ (100 cm) were $33.3 \text{ kg m}^{-2} \pm 9.7 \text{ kg m}^{-2}$ and $19.4 \text{ kg m}^{-2} \pm 3.7 \text{ kg m}^{-2}$ for polygon centres and rims, respectively. The polygons within the investigated area typically are about 15 m wide.

Analyzing the $S_{OC}$ (100 cm) on the soil subgroup level provided stock estimates ranging from $15.2 \text{ kg m}^{-2} \pm 4.6 \text{ kg m}^{-2}$ to $32.7 \text{ kg m}^{-2} \pm 10.4 \text{ kg m}^{-2}$. We, therefore, suggest that not only the SOC heterogeneity on the tundra biome scale needs to be captured in upscaling studies, but that more detailed field work is necessary to characterise site-scale SOC stock variations and how these may be successfully translated in upscaling approaches.

5.3 Vertical distribution of the soil organic carbon storage within the soil

Vertical distribution of carbon contents considerably differed between the two investigated geomorphic units. The volumetric organic carbon contents in the soils of the Holocene river terrace were rather uniformly distributed over the profiles’ depths whereas volumetric carbon contents in the soils of the floodplains were clearly highest in the uppermost 10 cm from the soil surface. This latter pattern probably is caused by the ongoing regular flooding events of the plains.

On the one hand, the floods bring allochthonous organic matter, which is deposited with the alluvium on the floodplains. On the other hand, the growing vegetation, which is regularly covered by the alluvium, is incorporated in the upper soil horizons.

High intensity of flooding including sometimes strong water currents moving over the flat plains located near the river shore prevents plant growth resulting in low volumetric soil organic carbon contents. When a certain elevation of the floodplains is reached caused by regular sedimentation, the intensity of flooding and current of water will decrease and, therefore, plants will be able to establish. This sparse vegetation at the elevated floodplain sites is only flooded periodically. As a consequence of these flooding events, the vegetation is covered by a fresh sediment layer which hinders the continuation of plant growth. These sediment layers are then populated by a new generation of plants and incorporate the prior canopy as peat into the top soil horizons resulting in high contents of carbon in the upper parts of soil horizons.

5.4 Permafrost soil organic carbon storage

We assigned estimated SOC stock data to the landscape units of Samoylov Island, averaged them by land unit and estimated the SOC pool size within the respective geomorphic unit for the whole Lena River Delta by multiplying with the area of the corresponding unit, particularly the areas of the Holocene river terrace and the active floodplains derived from our satellite image classification. Our estimates indicate that the Lena River Delta contains in total 241 Tg of SOC in the upper 1 m of soils within its river terrace and active floodplains. The SOC stock of the area-leading active floodplains levels is 120 Tg $\pm$ 66 Tg. Despite covering only about half as much area as the active floodplains, soils of the Holocene river terrace have a similar sized total SOC stock of 121 Tg $\pm$ 43 Tg. About one half of the estimated SOC stock of these two morphological units (127 Tg) occurs in the depth 0–50 cm which is the currently observed seasonal thaw depth in late summer. The organic carbon pool in the seasonally thawed top soil layer is subject to comparatively active decomposition and mineralization processes resulting in trace gas release to the atmosphere. On the other hand, this carbon pool gets also carbon inputs by fresh litter from the vegetation. First results of Höfle et al. (2012) indicate that physical protection mechanisms can limit SOC decomposition in the active layer.

The other portion of 113 Tg SOC (ca. 47 %) in the depth from 50–100 cm is currently excluded from intense soil-atmosphere exchange processes in the perennially frozen ground. Permafrost degradation resulting from higher temperatures and changed precipitation patterns leading to a deepening of the active layer are projected by global climate-permafrost models (Sazonova et al., 2004; Koven et al., 2011). The organic matter in the permafrost has been reported to be highly vulnerable to decay, and it is assumed...
that it has so far not undergone significant changes due to decomposition (Dutta et al., 2006; Khvorostyanov et al., 2008; Schuur et al., 2008, 2009; Waldrop et al., 2010). However, Knohl et al. (2013) argued that predictions of permafrost
organic matter vulnerability are probably overestimated because typically too much carbon has been assigned to the fast-cycling SOC pool. It is expected that portions of the near-surface permafrost will disappear by the end of this century (Lawrence et al., 2008). For large areas of the Lena River Delta the thickness of the seasonally thawed layer is expected to increase to 120 cm and for some areas even to 180 cm by the end of this century (Sazonova et al., 2004).

With the help of the Northern Circumpolar Soil Carbon Database (see Hugelius et al., 2013), we calculated a SOC pool for the whole Lena River Delta and the depth of 0–100 cm of 670 Tg carbon. When excluding the non-deltaic units, the SOC pool for the Holocene river terrace and the active floodplains was estimated to store around 357 Tg carbon in the depth of 0–100 cm. However, due to the given character of the database, we were neither able to exclude water bodies in the same way as done with our satellite imagery nor reduce the extent of the Holocene river terrace by the percentage of small water ponds and trough. Our reported carbon pool is lower with 241 Tg which might be an effect of the reduced spatial extent of the Holocene river terrace and the active floodplains we used for the upscaling. For robust estimates of the SOC pool in the circumpolar-arctic delta regions sampling must be performed in other major river deltas of this region.

5.5 Nitrogen stocks

The mean N stock estimate for the investigation area and the depth of 100 cm $S_N((100) \text{cm})$ amounted to 1.1 kg m$^{-2}$ or to 0.9 kg m$^{-2}$ and 1.2 kg m$^{-2}$, respectively, when the active floodplains and the river terrace are separately regarded. Jonasson et al. (1999) reported a N stock for arctic Scandinavian heath of 0.115 kg m$^{-2}$ and a depth of 15 cm, which theoretically can be recalculated for 100 cm depth amounting to 0.8 kg m$^{-2}$. For the eroding Alaska Beaufort Sea coastline, Ping et al. (2011) reported an average total N storage of 1.4 kg m$^{-2}$. The N stocks published by Harden et al. (2012) for 300 cm deep soil profiles of Gelisols were 4.6–7.5 kg m$^{-2}$. Assuming a homogeneous vertical N stock distribution, the $S_N((100) \text{cm})$ can be estimated at 1.5–2.5 kg m$^{-2}$ which is distinctly higher than the estimates of $S_N((100) \text{cm}$) in the Lena River Delta. The $S_N((100) \text{cm})$ found in our study was in the range of the stock estimates of Jonasson et al. (1999) and Ping et al. (2011).

Our estimates indicate that the Lena River Delta contains 12.5 Tg of N in the upper 1 m of soils within its Holocene river terrace and the active floodplain levels – reflecting a C/N ratio of about 20 (compare Table 4). About 49% of this N pool is not available for soil-vegetation-atmosphere interactions due to permanent fixation in the perennally frozen ground.

An increased deepening of the seasonally thawed layer (Sazonova et al., 2004; Koven et al., 2011) is likely to make this frozen storage of N better available to soil microorganisms. As a limiting nutrient for plant productivity, this additionally released N is likely to enhance the net primary production of existing vegetation by reducing the general N limitation of tundra plant communities (Shaver et al., 1986; Schimel et al., 1996; Weingraub and Schimel, 2003) or triggering a general change of species composition. However, it has to be considered that the portion of directly plant-available N within the amount of total N in soils is little as most N is contained in slow-cycling soil organic matter (Keuper et al., 2012).

6 Conclusions

The Lena River Delta, the largest arctic delta extends over an area of 32 000 km$^2$. We investigated SOC stocks of the Holocene river terrace and the active floodplain levels. Both together are the dominating geomorphic units in the Lena River Delta by area (62 % of the soil-covered area). The mean SOC stocks in the Holocene river terrace and the active floodplain are estimated at 29.5 kg m$^{-2}$ and at 13.6 kg m$^{-2}$, respectively. The Holocene river terrace stores about 50 % of the estimated SOC stock while occupying 32 % of the investigated portion of the Lena River Delta. Approximately 127 Tg of the estimated SOC mass of the river terrace and the active floodplains are stored in the seasonally thawed layer (0–50 cm depth). The SOC stock stored in permafrost (50–100 cm) and currently excluded from intense biogeochemical exchange with the atmosphere accounts for 113 Tg. Taking into account the projections for deepening of the seasonally thawed active layer and general degradation of permafrost over this century, this large stock is likely to become increasingly available for decomposition and mineralization processes as well as fluvial retransportation and offshore/onshore deposition in the future. With our study, we showed that the SOC stock in the Lena River Delta is high compared to average values reported for the tundra. However, the stocks are not as high as reported in the Northern Circumpolar Soil Carbon Database (see Hugelius et al., 2013) for the depth of 0–1 m, indicating that the total carbon storage in permafrost and the seasonally thawed layer of Arctic river deltas is probably lower than previously estimated, though still of substantial size. Here we investigated only the Holocene river terrace and active floodplain levels, and further complimentary investigations of the other geomorphic terraces that differ in cryostratigraphic composition and soils will be needed. In addition, we provide a first estimate of the total N stocks in this arctic river delta for the two investigated geomorphic units – the Holocene river terrace and the active floodplain levels – and the N pool sizes for the soils up to 100 cm in
the corresponding geomorphic units. We also report the N stocks on soil subgroup level with their depth distribution. With a mean of 13 Tg, the N stocks are higher than would be expected by assuming a general C/N ratio of 30 (Jonasson et al., 1999; Weintraub and Schimel, 2003) and considering our estimated SOC storage of 241 Tg. Though not investigated in detail within our investigation area, this large N pool deserves more consideration in future, particularly with regard to stocks of ammonium, nitrate and dissolved organic nitrogen.

Acknowledgement. This study was supported through the Cluster of Excellence “ CliSAP ” ( EXC177 ), University of Hamburg, funded through the German Research Foundation ( DFG ). Sebastian Zubrzycki was supported by a dissertation fellowship funded through the University of Hamburg ( HmbNFG ) and a grant founded through the German Academic Exchange Service “ DAAD ” PKZ: D/10/01863. Guido Grosse was supported by NASA grant NNX08A137G and NSF OPP-0732735 and received WorldView-1 imagery through the Polar Geospatial Center at University of Minnesota.

The authors thank the Lena River Delta Reserve, especially Aleksandr Gukov for the possibility to perform the study within the nature reserve. We thank the Alfred-Wegener-Institute in Potsdam and the “ Hydro-Base ” in Tiksi for logistical support. Special thanks go to Dmitri Bolshiyanov from the Arctic and Antarctic Research Institute, Irina Fedorova and Vladimir Churun from the Otto-Schmidt-Laboratory in St. Petersburg for using their laboratory facilities and help.
