Abstract. It has been proposed that ocean acidification (OA) will interact with other environmental factors to influence the overall impact of global change on biological systems. Accordingly we investigated the influence of nitrogen limitation and OA on the physiology of diatoms by growing the diatom *Phaeodactylum tricornutum* Bohlin under elevated (1000 µatm; high CO\(_2\) – HC) or ambient (390 µatm; low CO\(_2\) – LC) levels of CO\(_2\) with replete (110 µmol L\(^-1\); high nitrate – HN) or reduced (10 µmol L\(^-1\); low nitrate – LN) levels of NO\(_3\)\(^-\) and subjecting the cells to solar radiation with or without UV irradiance to determine their susceptibility to UV radiation (UVR, 280–400 nm). Our results indicate that OA and UVB induced significantly higher inhibition of both the photosynthetic rate and quantum yield under LN than under HN conditions. UV A or/and UVB increased the cells’ non-photochemical quenching (NPQ) regardless of the CO\(_2\) levels. Under LN and OA conditions, activity of superoxide dismutase and catalase activities were enhanced, along with the highest sensitivity to UVB and the lowest ratio of repair to damage of PSII. HC-grown cells showed a faster recovery rate of yield under HN but not under LN conditions. We conclude therefore that nutrient limitation makes cells more prone to the deleterious effects of UV radiation and that HC conditions (ocean acidification) exacerbate this effect. The finding that nitrate limitation and ocean acidification interact with UV-B to reduce photosynthetic performance of the diatom *P. tricornutum* implies that ocean primary production and the marine biological C pump will be affected by OA under multiple stressors.

1 Introduction

Increasing atmospheric levels of CO\(_2\) and the associated dissolution of CO\(_2\) into the oceans has resulted in ocean acidification (OA), with increased levels of pCO\(_2\), HCO\(_3\)\(^-\) and H\(^+\) and decreased CO\(_3\)\(^2-\) concentration. The acidity of surface oceans has increased by 30 % (lowering pH by 0.1) since the Industrial Revolution and is expected to increase by 100–150 % (0.3–0.4 pH) by the year 2100 (Orr et al., 2005). At the same time, increased sea surface temperatures are predicted to cause a shoaling of the surface mixed layer, which in turn will lead to enhanced exposure to sunlight (both as photosynthetically active radiation (PAR) and as UV radiation (UVR)). This enhanced stratification will also decrease upward transport of nutrients from deeper, nutrient-rich layers, leading to more frequent/marked nutrient limitation (Cermeño et al., 2008). Global change is thus likely to cause changes in a multiplicity of factors that influence phytoplankton growth and it is thus critical to examine OA in the context of interactive effects with these other environmental drivers (Boyd, 2011). Increased availability of CO\(_2\) in seawater appears in some cases to bring a low level of benefit to growth and photosynthesis of natural phytoplankton populations (Riebesell and...
Tortell, 2011, and references therein), though in most cases laboratory experiments have shown little effect of OA alone (Doney et al., 2009). However, the effects can differ according to changes in solar radiation and/or other physical or chemical factors (Gao et al., 2012a). Increased acidity of seawater may lead to physiological stress (Pörtner and Farrell, 2008) and affect phytoplankton nutrient uptake (Beman et al., 2011; Shi et al., 2012). Therefore, OA could most likely result in differential effects on different photosynthetic organisms or under different environmental conditions (Gao, 2011).

Diatoms account for about 20% of total global primary production and about 40% of that in the oceans (Granum et al., 2005). Early reports suggested that growth of diatom species could be limited by the availability of CO2 (Riebesell et al., 1993). However, the growth rate of diatom-dominated natural phytoplankton populations was not affected by CO2 enrichment to 800 µatm (Tortell, 2000), and not all diatom species were sensitive to seawater pCO2 rise under nutrient-replete conditions in a mesocosm study (Kim et al., 2006). In laboratory experiments, growth of Skeletonema costatum was not stimulated by elevated CO2 (800 µatm; Chen and Gao, 2011). Phaeodactylum tricornutum grown under nitrate-limited conditions also showed no enhancement of growth under high CO2 (1000 µatm; Li et al., 2012a). Nevertheless, in other work, the diatoms Phaeodactylum tricornutum (1000 µatm; Wu et al., 2010) and Atthephya sp. (670 µatm; King et al., 2011) showed enhanced growth rate in nutrient-replete conditions under elevated CO2 levels. These variable findings reflect physiologically differential responses among different species or under different experimental or environmental conditions. Changes in light intensity can lead to enhanced, unaffected or inhibited growth rates under OA conditions, even for the same diatom species (Gao et al., 2012b). Recently, microcosm studies have shown that the species abundance and physiological responses (e.g., Chl a, DNA damage, reactive oxygen species (ROS), photosynthetic efficiency) could be regulated by nutrients and light availability under high CO2 conditions (Neale et al., 2014; Sobrino et al., 2014). Therefore, the effects of OA should be considered in the context of the influence of multiple factors, such as temperature, nutrient status, light and UVR (Boyd, 2011; IPCC, 2011; Gao et al., 2012a).

Solar UVB radiation (280–400 nm) is increasing due to interactions of global change and ozone depletion (Häder et al., 2011), is known to damage DNA (Buma et al., 2003; Gao et al., 2008), lower photosynthetic rates (Helbling et al., 2003), perturb the uptake of nutrients (Hessen et al., 2008) and alter morphological development (Wu et al., 2005) of phytoplankton. In contrast, under moderate levels of solar radiation, solar UVA radiation (315–400 nm) is known to stimulate photosynthesis (Gao et al., 2007), signaling (Cashmore, 1998) and photo-repair of UVB-induced damage (Buma et al., 2003) in phytoplankton. Previously, it was shown that UV-induced inhibition of dinoflagellates was lower under nutrient-replete conditions but higher under nutrient limitation due to less efficient repair resulting from lowered nutrient availability (Litchman et al., 2002). Similar enhancement of UVB impacts under nutrient (N, P) limitation were shown for a green microalga, Dunaliella tertiolecta (Shelly et al., 2002; Heraud et al., 2005). Recently, OA was found to enhance UVB-induced damage to a red tide alga, Phaeocystis globosa, leading to a greater decrease in growth rate and photochemical yield under 1000 µatm CO2 (Chen and Gao, 2011).

Marine phytoplankton often experience nutrient limitation in offshore waters; with progressive ocean warming, such limitation will be intensified due to the decreased depth of the surface mixed layer (enhanced stratification) (Cermeño et al., 2008). Combined effects of nutrient levels and CO2 have been reported in many studies. For example, photosynthetic carbon fixation of the coccolithophorid Emiliania huxleyi was enhanced under high light and low nitrogen conditions when the seawater CO2 concentration was raised to 2000 µatm (Leonardos and Geider, 2005). However, increased seawater CO2 concentration also showed antagonistic effects with iron in modulating (down- or up-regulating) primary production of marine phytoplankton in the Gulf of Alaska (a nutrient-replete but low-chlorophyll area) (Hopkinson et al., 2010). In some toxin producing species, for example the dinoflagellate Karlodinium veneficum, toxicity was enhanced under high CO2 and low phosphate conditions (Fu et al., 2010). However, to the best of our knowledge, there is little information concerning the combined effects of OA and NO3− limitation on diatoms and their susceptibility to damage from solar UVR (280–400 nm).

Nutrient availability can influence phytoplankton responses to UV and to CO2-induced seawater acidification. Theoretically, increased seawater acidity can perturb the intracellular acid–base balance and thus lead to differential interactions between nutrients and solar UVR. In this study, we hypothesize that reduced availability of NO3− under OA would affect the photosynthetic performance under solar radiation with or without UVB. We used the diatom Phaeodactylum tricornutum to test this hypothesis.

2 Materials and methods

2.1 Growth conditions

The diatom Phaeodactylum tricornutum Bohlin (strain CCMA 106), isolated from the South China Sea (SCS) and maintained in the Center for Collections of Marine Bacteria and Phytoplankton (CCMBP) of the State Key Laboratory of Marine Environmental Sciences (Xiamen University), was grown mono-specifically in artificial seawater enriched with Aquil medium (Morel et al., 1979). Cells were cultured in 500 mL vessels containing 250 mL of medium under two levels of NO3− (110 µmol L−1, high nitrate – HN
and 10 µmol L\(^{-1}\), low nitrate – LN) and aerated with ambient (outdoor) air (low CO\(_2\) – LC; 390 µatm) or elevated (1000 µatm; high CO\(_2\) – HC) CO\(_2\) levels within a plant CO\(_2\) chamber (HP1000G-D, Ruizhua Instrument and Equipment Co. Ltd, China). Gas flow rate was 300 mL min\(^{-1}\), and the CO\(_2\) concentrations varied by less than 3% of the target value. The low NO\(_3\) level of 10 µmol L\(^{-1}\) was based on its concentration range (ca. 0–20 µmol L\(^{-1}\)) in the oligotrophic SCS, from where the diatom strain was isolated. Dilutions were made every 24 h, so that the seawater carbonate system was kept stable under each CO\(_2\) level within the cell density range of 6 × 10\(^4\) to 3 × 10\(^5\) cells mL\(^{-1}\) (exponential growth phase). According to the pre-experiment, the initial nitrate concentration of 10 µmol L\(^{-1}\) could be totally consumed (0–10 µmol L\(^{-1}\)) and the initial nitrate concentration of 110 µmol L\(^{-1}\) treatment ranged from ca. 85–110 µmol L\(^{-1}\) during the culture. The cells were grown at 70 µmol photons m\(^{-2}\) s\(^{-1}\) (cool white fluorescent tubes) under a 12L : 12D photoperiod for at least 10 generations before being used for the solar radiation treatments described below. Three independent cultures were grown at each set of conditions.

### 2.2 Determination of seawater carbonate system parameters

The pH in the cultures was determined daily during the light period with a pH potentiometric titrator (DL15, Mettler-Toledo, Schwerzenbach, Switzerland), which was calibrated with NBS (National Bureau of Standards) buffer solutions (Hanna). DIC (dissolved inorganic carbon) was estimated with an automatic system (AS-C3, Apollo Scitech) linked to an infrared gas detector (Li-Cor 7000, Li-Cor). DIC, pH, nutrient concentrations (phosphate, 10 µmol L\(^{-1}\); silicate, 100 µmol L\(^{-1}\)); salinity (35) and temperature (20°C) were used to calculate the parameters of the seawater carbonate system (HCO\(_3\)\(^{-}\), CO\(_3\)\(^{2-}\), CO\(_2\) and TA) using the CO\(_2\) system analyzing software CO\(_2\)SYS (Lewis and Wallace, 1998) as described previously (Li et al., 2012a). The carbonic acid dissociation constants (\(K_1\) and \(K_2\)) used were those of Roy et al. (1993), and that for boric acid (\(K_B\)) was from Dickson (1990).

### 2.3 Radiation treatments under the solar simulator

To determine the effects of growth conditions on the sensitivity of carbon fixation and chlorophyll fluorescence to short-term exposure to UVR, *P. tricornutum* cells, grown under LC–LN, HC–LN, LC–HN and HC–HN conditions, were exposed for 1 h to different radiation treatments with or without UVR, as follows: (1) PAR treatment, tubes wrapped with Ultraphan film 295 (Digefra, Munich, Germany) so that the cells received wavelengths above 295 nm (PAR + UVA + UVB). The transmission spectra of the cut-off filters are available elsewhere (Zheng and Gao, 2009). Samples were placed at a distance of 1.2 m from a solar simulator (Sol 1200W, Dr. Höhle, Martinsried, Germany), so that the actual PAR light intensity to which the cells were exposed were within the tubes (calculated taking into account the transmission properties of the quartz tubes and the filters) was 44.11 W m\(^{-2}\) (ca. 190.11 µmol photons m\(^{-2}\) s\(^{-1}\)) which is close to the daytime mean photon flux in the middle of the photic zone (22–36 m depth in South China Sea, SEATS station). The corresponding UVA and UVB irradiances were 14.19 W m\(^{-2}\) (ca. 41.99 µmol photons m\(^{-2}\) s\(^{-1}\)) and 0.75 W m\(^{-2}\) (ca. 1.89 µmol photons m\(^{-2}\) s\(^{-1}\)). Irradiances were measured with a broadband filter radiometer (ELDONET, Real Time Computer, Möhrendorf, Germany). After the radiation treatments, the cells were replaced under their growth light level (70 µmol photons m\(^{-2}\) s\(^{-1}\)) to examine the recovery of photosynthetic performance. During the incubations, the tubes were maintained in a water bath at 20°C using a circulating cooler (Eyela, CAP-3000, Tokyo Rikakikai Co. Ltd., Tokyo, Japan).

### 2.4 Measurement of carbon fixation

The \(^{14}\)C method was applied to measurements of marine photosynthetic carbon fixation (Nielsen, 1952), and has been detailed with modified protocols in many publications (Holm-Hansen and Helbling, 1995; Gao et al., 2007). Cells were harvested in the middle of the light phase, diluted with freshly made medium equilibrated with the designated concentrations of CO\(_2\) to a cell concentration of 2–3 × 10\(^4\) cells mL\(^{-1}\) and transferred to 35 mL quartz tubes. Each tube was injected with 100 µL–5 µCi (0.185 MBq) NaH\(^{14}\)CO\(_3\) solution (ICN Radiochemicals). Triplicate incubations were carried out for each treatment as mentioned above and, additionally, three tubes were wrapped in aluminum foil and incubated as a dark control. The cells were collected on Whatman GF/F glass filters either immediately after 1 h exposure to the solar simulator or after a period of recovery under their growth light for another hour. The filters were put into 20 mL scintillation vials, fumed with HCl for 12 h and then dried for 6 h at 45°C to expel the non-fixed inorganic carbon as CO\(_2\). Scintillation cocktail (3 mL of Tri-Carb 2800TR, Perkin Elmer\(^{®}\)) was added to the vials, and radioactivity in the vials counted with a liquid scintillation counter (LS 6500, Beckman Coulter, USA). Carbon fixation rates were calculated from these values and are presented on a per cell or per Chl \(a\) basis.

### 2.5 Measurement of chlorophyll fluorescence

For chlorophyll fluorescence measurements, cell collection and radiation treatments were carried out as described above. The effective quantum yield was measured every 20 min ei-
ther during the solar simulator exposure or during recovery under the growth light level.

The effective quantum yield and non-photochemical quenching (NPQ) parameters were calculated according to Genty et al. (1990) as yield = (Fm′ − F0)/Fm′ and NPQ = (Fm − Fm′)/Fm′, respectively, where Fm′ is the maximum fluorescence yield after 15 min dark adaptation, Fm is the light-adapted maximal chlorophyll fluorescence yield measured during the exposures and F0 is the steady fluorescence level during the exposures. The actinic light was set at the growth light level, and the saturating pulse (5000 µmol photons m−2 s−1) lasted for 0.8 s.

Repair (r) and damage (k) rates during the 60 min exposure period in the presence of UV were calculated using the Kok model (Heraud and Beardall, 2000): P/P0 = r/(k + r) + [k/(k + r)]e−(k+r)t, where P0 and P were the yield values at the beginning and at exposure time t.

During the recovery period, the exponential rate constant for recovery (R) was calculated from the following equation: y = y0 + b × [1 − exp(−R × t)], where y represents the yield value at time t, y0 is the starting value before recovery and b is a constant.

The relative inhibitions of carbon fixation or yield caused by UVA or UVB were calculated as follows:

\[
\text{Inh}_{\text{UVR}} = \left( \frac{P_{\text{PAR}} - P_{\text{PAB}}}{P_{\text{PAR}}} \right) \times 100\%,
\]

\[
\text{Inh}_{\text{UVA}} = \left( \frac{P_{\text{PAR}} - P_{\text{PA}}}{P_{\text{PAR}}} \right) \times 100\%,
\]

\[
\text{Inh}_{\text{UVB}} = \text{Inh}_{\text{UVR}} - \text{Inh}_{\text{UVA}};
\]

where \( P_{\text{PAR}} \), \( P_{\text{PA}} \) and \( P_{\text{PAB}} \) represent carbon fixation or yield values under PAR, PAR + UVA, PAR + UVA + UVB treatments, respectively.

2.6 Cells counts and chlorophyll a measurements

The cells were counted using a Z2™ Coulter Counter (Beckman, USA). Where needed, we used the values for chlorophyll a (Chl a) contents of the cells grown under the same CO2 and nitrate levels reported previously (Li et al., 2012a).

2.7 Total protein content, superoxide dismutase (SOD) and catalase (CAT) measurements

To determine the total protein content and activities of superoxide dismutase (SOD) and catalase (CAT), cells were collected, in the middle of the light phase, onto a polycarbonate membrane (0.22 µm, Whatman) under vacuum at a pressure of less than 0.01 MPa and washed into a 1 mL centrifuge tube with phosphate buffer (pH 7.6). The enzyme extractions were carried out in 0.6 mL phosphate buffer (pH 7.6) that contained 50 mM KH2PO4, 1 mM ethylenediaminetetraacetic acid (EDTA), 0.1% Triton X-100 and 1% (w/v) polyvinylpyrrolidone. The cells were broken by sonication in an ice-water bath (4 °C), and the homogenized extract was centrifuged at 12 000 g (4 °C) for 10 min before the activities of SOD and CAT were tested with SOD and CAT Assay Kits (Nanjing Jiancheng Biological Engineering Company, China). One unit of SOD was defined as the amount causing a 50% inhibition of nitroblue tetrazolium (NBT) reduction (Wang and Wang, 2010). One unit of CAT activity was defined as the amount required to decompose 1 µmol H2O2 per second. The SOD and CAT activities were expressed as U mg−1 protein and per 106 cells (Fig. S1 in the Supplement). The total protein content was determined according to Bradford (1976) using bovine serum albumin as the standard.

2.8 Statistical analyses and calculations

One-way analysis of variance (ANOVA) was used, followed by a multiple comparison using a Tukey test to establish differences among the treatments. Interactive effects among CO2, NO3− and UVR on carbon fixation and yield were determined using a two- or three-way ANOVA to establish significant differences among the variables.

3 Results

3.1 Carbon fixation

Carbon fixation was significantly inhibited by UVR in both HN and LN-grown cells on either a per cell or per Chl a basis (Fig. 1). Under the HN conditions, the carbon fixation rates of LC and HC cultures, compared to that of the PAR alone treatment, were inhibited by 29.4% (\( P = 0.0002 \)) and 36.7% (\( P < 0.0001 \)) in the presence of UVA (PA treatment: PAR + UVA), and by 47.7% (\( P < 0.0001 \)) and 46.1% (\( P = 0.0029 \)) with both UVA and UVB (PAB, PAR + UVA + UVB) (Fig. 1a and c). However, the carbon fixation per cell in the LC-grown cells was 10.0% (\( P = 0.0058 \)) higher in those exposed to PA, and fixation based on Chl a was higher under the PAR alone or PA treatments, by about 8.4 (\( P = 0.0253 \)) and 17.9% (\( P = 0.005 \)) compared to that of the HC-grown cells. For PAB treatments, there were no significant differences between the HC- and LC-grown cells (Fig. 1a and c).

Under LN conditions, carbon fixation rates of LC- and HC-grown cells were decreased by 14.7 (\( P = 0.0039 \)) and 1.1% (\( P = 0.8658 \)) in the presence of UVA (PA) and by 23.3 (\( P = 0.0019 \)) and 27.3% (\( P = 0.0123 \)) with both UVA and UVB (PAB, PAR + UVA + UVB) treatments, respectively (Fig. 1b and d), compared with that of PAR alone treatment. This indicates that both UVA and UVB resulted in significant impacts on the LN-grown cells under LC, but only UVB brought about a significant reduction of the rate under HC. In the PA treatment, the HC–LN cells fixed carbon at a rate 21.7% (\( P = 0.0071 \)) higher than in the LC–LN cells (Fig. 1b), however, there were no significant differences between HC and LC cells in the PAR and the PAB treatments under N limitation. Under the LN level, the carbon fixation rate per Chl a was about
30.8 \( (P = 0.01) \), 51.6 \( (P = 0.0013) \) and 24.0\% \( (P = 0.03) \) higher in HC-grown than in LC-grown cells (Fig. 1d).

### 3.2 Photochemical quantum yield

When exposed to different irradiation treatments, photochemical quantum yields in the cells grown under either HC or LN conditions showed similar patterns to those grown at LC and HN conditions (Fig. 2), decreasing rapidly during the initial 20 min and leveling off after 40 to 60 min. Under HN conditions, the yield in the HC-grown cells decreased to a similar level among the treatments (PAR, \( P = 0.1568 \); PA, \( P = 0.0879 \); PAB, \( P = 0.1341 \)) as that in the LC treatments (Fig. 2a and b). Under the LN condition, the yield decreased to much lower levels compared to those under LN treatments (Fig. 2c and d). Cells exposed to all treatments showed recovery of the yield, under their growth light (70 \( \mu \)mol photons m\(^{-2}\) s\(^{-1}\)), to approximately their initial levels in about 80 min (Fig. 2).

### 3.3 UVA- and UVB-induced inhibition of photosynthetic performance

While UVA induced significantly higher \( (P = 0.0114) \) inhibition of photosynthetic carbon fixation in the HC–HN-grown cells, but lower \( (P = 0.0038) \) in the HC–LN-grown cells (Fig. 3a and b), it did not cause significant changes in the yield between the HC- and LC-grown cells (HN, \( P = 0.1375 \); LN, \( P = 0.0500 \)) (Fig. 3c and d). While the contribution of UVB did not induce significant inhibition of either carbon fixation \( (P = 0.2308) \) or yield \( (P = 0.5319) \) in the HN-grown cells, under both the HC and LC conditions (Fig. 3a and c), it caused significantly higher inhibition of the photosynthetic rate \( (by\ 203.3\%\ , \ P = 0.0006) \) and the yield \( (by\ 76.8\%\ , \ P = 0.0451) \) in the HC-grown than the LC-grown cells under \( NO_3^- \)-limited conditions (Fig. 3b and d). Interactive effects among \( CO_2\ , \ NO_3^- \) and radiation treatments on yield were significant (Table 1).

### 3.4 Repair, damage rates and constant for recovery rate

The HC-grown cells had higher rates of damage, \( k \), than the LC-grown cells under nitrogen limitation but not under N-replete conditions (HN, \( P = 0.2109 \); LN, \( P = 0.0092 \); Table 2). No effect was observed for repair rates \( r \) (HN, \( P = 0.1655 \); LN, \( P = 0.5276 \); Table 2). The repair: damage ratios \( (r/k) \) in the HC-grown cells showed a 21.0\% \( (but\ statistically\ insignificant) \) increase under HN \( (P = 0.3450) \) but decreased significantly by 31.1\% \( under\ LN\ (P = 0.0320) \) conditions, compared to the LC-grown cells, respectively (Table 2). Under the low PAR, the exponential rate constant for recovery \( (R) \) showed dependency on previous light treatments with a lowered rate in the cells exposed to UVR, while HC stimulated the rate under the HN but not LN conditions (Table 3). Obviously, the cells exposed to the radiation treatments with UVB took longer \( (P<0.05) \) to recover their photochemical yield, and pre-exposure to UVA had lit-
Table 1. Interactive effects among NO₃⁻ concentrations, CO₂ levels and radiation treatments. Figure 3. UV-induced inhibition of carbon fixation and PSII activity. UVA- and UVB-induced inhibition of (a, b) photosynthetic carbon fixation and (c, d) PSII of P. tricornutum cells grown at ambient (390 µatm, LC) or elevated CO₂ (1000 µatm, HC) under (a, c) NO₃⁻-replete (110 µmol L⁻¹, HN) and (b, d) NO₃⁻-limited (10 µmol L⁻¹, LN) conditions when exposed to PAR, PAR + UVA (PA) and PAR + UVA + UVB (PAB) for 60 min, respectively. The irradiance intensity under solar simulator was the same as mentioned above. Vertical bars are means ± SD, \( n = 3 \), the different letters indicate significant differences between different treatments at \( P < 0.05 \) level.

Figure 4. Non-photochemical quenching (NPQ) of P. tricornutum under different treatments. NPQ of P. tricornutum grown at ambient (390 µatm, LC) or elevated CO₂ (1000 µatm, HC) under (a, b) NO₃⁻-replete (110 µmol L⁻¹, HN) and (c, d) NO₃⁻-limited (10 µmol L⁻¹, LN) conditions when exposed to PAR, PAR + UVA (PA) and PAR + UVA + UVB (PAB) for 60 min and another 80 min under the growth light level, respectively. The irradiance intensities under solar simulator or growth light were the same as mentioned above. Vertical bars means ± SD, \( n = 3 \).
and d). Lower NPQ values were found in HN-grown cells in LN-grown cells, regardless of the CO$_2$ level (Fig. 4a and b). Similar trends were found in both the LN- and HN-grown cells regardless of the radiation treatments (Fig. 4). Both UVA and UVB caused additional ($P<0.05$) rises in NPQ in HN-grown cells regardless of the CO$_2$ levels (Fig. 4a and b). However, neither UVA nor UVB induced significant ($P>0.05$) change in NPQ in LN-grown cells, regardless of the CO$_2$ levels (Fig. 4c and d). Lower NPQ values were found in HN-grown cells compared with LN, under either PAR alone or PAR + UVA treatments. The addition of UVB, however, resulted in an approximately 17.0 % higher, but statistically insignificant (LC, $P = 0.1150$; HC, $P = 0.1660$), increase of NPQ in HN-grown compared to LN-grown cells. Transfer to the growth light level without UV, to allow for recovery, led to a rapid decline of NPQ with time. For the cells that were pre-exposed to the PAR + UVA + UVB treatment, relaxation of NPQ during the recovery period showed no difference ($P>0.05$) between HC- and LC-grown cells except that NPQ in the HC--HN-grown cells declined faster ($P = 0.0242$) than in LC--HN cells. Two-way ANOVA showed that both nitrogen levels and radiation treatments individually, and also interactively, affected the NPQ (Table 1).

### 3.5 Non-photochemical quenching (NPQ)

Non-photochemical quenching (NPQ) showed the opposite pattern of change to yield during both the exposure and recovery periods (Fig. 4). Under HN conditions, HC treatments triggered the highest NPQ within 20 min, while NPQ reached its maximal values at 40 min under the ambient (LC) CO$_2$ level (Fig. 4a and b). However, neither UVA nor UVB induced significant ($P>0.05$) change in NPQ in HN-grown cells, regardless of the CO$_2$ levels (Fig. 4a and b). Lower NPQ values were found in LN-grown cells compared with LN, under either PAR alone or PAR + UVA treatments. The addition of UVB, however, resulted in an approximately 17.0 % higher, but statistically insignificant (LC, $P = 0.1150$; HC, $P = 0.1660$), increase of NPQ in HN-grown compared to LN-grown cells. Transfer to the growth light level without UV, to allow for recovery, led to a rapid decline of NPQ with time. For the cells that were pre-exposed to the PAR + UVA + UVB treatment, relaxation of NPQ during the recovery period showed no difference ($P>0.05$) between HC- and LC-grown cells except that NPQ in the HC--HN-grown cells declined faster ($P = 0.0242$) than in LC--HN cells. Two-way ANOVA showed that both nitrogen levels and radiation treatments individually, and also interactively, affected the NPQ (Table 1).

### 3.6 Protein content, SOD and CAT activities

Protein contents were enhanced in HN cultures under both LC (3.21 ± 0.98 pg cell$^{-1}$) and HC (3.38 ± 1.35 pg cell$^{-1}$) conditions, compared with LN-grown cells (LC, 2.58 ± 0.46 pg cell$^{-1}$; HC, 2.28 ± 0.68 pg cell$^{-1}$), though statistically there were no significant differences among the treatments ($P = 0.4296$) (Fig. 5a). There was no significant difference in protein content between LC and HC treatments at a given NO$_3^-$ concentration. However, NO$_3^-$ limitation enhanced SOD (LC, by 62.5 %, $P = 0.0004$; HC, by 72.5 %, $P = 0.0007$) and CAT (LC, by 67.5 %, $P = 0.0759$; HC, by 67.1 %, $P = 0.0747$) activities in both LC- and HC-grown cells, when based on protein content (Fig. 5b and c), though such enhancement was insignificant ($P>0.1$) when normalized to per cell (Fig. S1).

### 4 Discussion

This study shows that nitrate limitation interacts with OA to affect the overall impacts of solar UVR on the diatom *P. tricornutum*. OA and UVB caused significantly higher inhibition of the photosynthetic rate and the quantum yield under LN than under HN conditions. Interactive effects of reduced nitrate availability and OA increased protein-based activity of superoxide dismutase (SOD) and catalase (CAT) but decreased the rate of repair of PSII from UV-induced damage. OA appeared to counteract UVB-induced damage under NO$_3^-$-replete conditions, but when combined with decreased availability of nitrate, it increased the diatom’s sensitivity to UVR.

Most diatoms have evolved CO$_2$ concentrating mechanisms (CCMs) as a response to low availability of CO$_2$ in present-day oceans (Raven et al., 2011). Increasing $p$CO$_2$ may, to some extent, benefit marine phytoplankton due to in-

creased CO$_2$ availability, with short-term acclimated cells showing a linear correlation with changes in $f$CO$_2$, although this was not the case in long-term acclimated cells (Hennon et al., 2014). On the other hand, the down-regulation of CCM operation was recently shown to decrease the growth of three diatoms (Phaeodactylum tricornutum, Thalassiosira pseudonana and Skeletonema costatum) under high levels of sunlight but to enhance it under low light (Gao et al., 2012b). The growth rate of P. tricornutum under high CO$_2$ (1000 µatm) decreased at light levels higher than 180 µmol m$^{-2}$ s$^{-1}$ to reach growth rate values lower than that of the low CO$_2$-grown cells (Gao et al., 2012b). In the present study, under the near-saturation light level (ca. 190 µmol photons m$^{-2}$ s$^{-1}$ of PAR), photosynthetic carbon fixation rate per Chl $a$ under nitrate-limited conditions were higher in the HC-grown cells. Obviously, the nutrient limitation influenced the effects of OA.

UVR is known to damage photosynthetic pigments and proteins (for example D1 and rubisco proteins; Zacher et al., 2007) and therefore can reduce the photosynthetic capacity of algae (Häder et al., 2011). UVA induced significantly higher inhibition of carbon fixation in HC–HN- than in LC–HN-grown cells, reflecting a synergistic effect of UVA and OA; however, for the same cells, UVB induced no greater inhibition of the photosynthetic carbon fixation in HC compared to LC cells, which is in contrast to the findings reported in another study (Li et al., 2012b). Many studies have shown that the sensitivity of cells to high levels of PAR and UV under OA conditions could be stimulated and then induce higher inhibition rate of photosynthesis (Sobrino et al., 2008; Gao et al., 2012b; Xu and Gao, 2012). However, this phenomenon is not always found in all species especially when the intensity of PAR or UV is not that high. For example, a recent study reported that the unicellular chlorophyte Dunaliella tertiolecta acclimated with high CO$_2$ under nutrient-replete conditions could alleviate the stress induced by high PAR and UV (García-Gómez et al., 2014). This could be due to energy saving as a result of down-regulation of CCM activity. However, in the present study, we did not find that the synergistic effects of OA and UVR induced a higher inhibition at the light intensity of PAR + UVA + UVB (44.11 + 14.19 + 0.75 Wm$^{-2}$) used, than found under LC. This may be due to the light intensity of PAR or UVR not being high enough to exceed the energy dissipating capacity of the cells. Furthermore, under high N the nutrient supply would be sufficient to support the repair processes of UV- or high-PAR-induced damage. In the LN-grown cells, UVB induced greater inhibition of both carbon fixation and yield, probably due to a decreased repair/damage ratio (Table 2) and decreased levels of both Chl $a$ and other light-harvesting pigments (Li et al., 2012a) since the (re)synthesis of both proteins and UV-screening compounds depends on nitrogen availability (Beardall et al., 2009, 2014). Such an inhibition by UVB in LN-grown cells was more pronounced under OA conditions (Fig. 3b and d), though UVB appeared to counteract the OA effect under the HN condition. When the

**Figure 5.** Protein contents, SOD and CAT activities of P. tricornutum under different treatments. (a) Protein contents, (b) SOD and (c) CAT activities (represented as per milligram protein) of P. tricornutum grown at ambient (390 µatm, LC) or elevated CO$_2$ (1000 µatm, HC) under NO$_3^−$-replete (110 µmol L$^{-1}$, HN) or NO$_3^−$-limited (10 µmol L$^{-1}$, LN) conditions. The different letters above each column indicate significant differences between different treatments at $P < 0.05$ level. Vertical bars show mean ± SD, except the CAT value in HC–LN for which there were only two replicates, other treatments used at least three replicates ($n = 3–7$).
cells are exposed to lower external pH, they need additional energy to cope with the acid–base perturbation (Kanazawa and Kramer, 2002). By impairing photosynthesis, nitrogen limitation could decrease the supply of energy, especially in the presence of UVB (Döhler, 1998). Though SOD and CAT normalized per cell showed no change in all treatments (Fig. S1), the fact that nitrogen limitation led to decreased protein contents per cell and with higher activity of SOD and CAT (based on protein content) implies that these enzymes are preferentially retained in the face of decreasing protein per cell and thus reflects an enhanced defense strategy (Fig. 5), so that ROS that were formed under N limitation could be scavenged. The differential impacts of UVB on HN and LN-grown cells under the OA treatment could be due to differences in the repair and damage rates (Table 2) and differential stimulation of periplasmic proteins (Wu and Gao, 2009), which are important transporters of ions and play important roles in maintaining intracellular acid–base stability. On the other hand, NO$_3^-$ scarcity usually leads to an impaired PSII reaction center activity due to decreased synthesis of key proteins, therefore, leading to decreased quantum yields of PSII (Geider et al., 1993). In this study, _P. tricornutum_ key proteins, therefore, leading to decreased quantum yields PSII reaction center activity due to decreased synthesis of for diatoms, such as _P. tricornutum_ in influencing marine primary production (Gao et al., 2012a). and increased solar exposures will become the main drivers zones, and interactions of enhanced nutrient limitation, OA nutrients will be transported from deeper layers to the photic induced inhibition of photosynthesis was found in pelagic inorganic nitrogen concentrations range from 0–20 µmol, in the presence of UVB on HN and LN-grown cells under the OA treatment could be due to in the nitrogen-limited cells (Fig. 4c and d), indicating smaller and lower heat dissipating capability, when combined with the OA treatment, consistent with these cells having the highest damage and the lowest repair (Table 2). In the HN-grown cells, better recovery of both photosynthetic carbon fixation (data not shown) and photosynthetic performance (Tables 3 and 4) under OA conditions could be attributed to faster repair rate of PSII and related metabolic up-regulations.

The results from the present work suggest that nutrient limitation can alter the effects of OA or UVR and their interactions. In the oligotrophic oceans, such as the surface mixed layers of the South China Sea (SCS), where averaged total inorganic nitrogen concentrations range from 0–20 µmol, UVB and OA can act synergistically to bring about a higher inhibition of photosynthetic carbon fixation. Higher UVB-induced inhibition of photosynthesis was found in pelagic low-nutrient waters than in coastal waters in the SCS (Li et al., 2011). With enhanced stratification and reduced thickness of the upper mixed layer due to ocean warming, fewer nutrients will be transported from deeper layers to the photic zones, and interactions of enhanced nutrient limitation, OA and increased solar exposures will become the main drivers influencing marine primary production (Gao et al., 2012a). For diatoms, such as _P. tricornutum_, OA and other ocean changes may result in transitions in their vertical and horizontal distributions and changes in phytoplankton community structure.
