Abstract. Increasing atmospheric carbon dioxide (CO\textsubscript{2}) is changing seawater chemistry towards reduced pH, which affects various properties of marine organisms. Coastal and brackish water communities are expected to be less affected by ocean acidification (OA) as these communities are typically adapted to high fluctuations in CO\textsubscript{2} and pH. Here we investigate the response of a coastal brackish water plankton community to increasing CO\textsubscript{2} levels as projected for the coming decades and the end of this century in terms of community and biochemical fatty acid (FA) composition. A Baltic Sea plankton community was enclosed in a set of offshore mesocosms and subjected to a CO\textsubscript{2} gradient ranging from natural concentrations (∼ 347 µatm \textit{f}CO\textsubscript{2}) up to values projected for the year 2100 (∼ 1333 µatm \textit{f}CO\textsubscript{2}). We show that the phytoplankton community composition was resilient to CO\textsubscript{2} and did not diverge between the treatments. Seston FA composition was influenced by community composition, which in turn was driven by silicate and phosphate limitation in the mesocosms and showed no difference between the CO\textsubscript{2} treatments. These results suggest that CO\textsubscript{2} effects are dampened in coastal communities that already experience high natural fluctuations in \textit{p}CO\textsubscript{2}. Although this coastal plankton community was tolerant of high \textit{p}CO\textsubscript{2} levels, hypoxia and CO\textsubscript{2} uptake by the sea can aggravate acidification and may lead to pH changes outside the currently experienced range for coastal organisms.

1 Introduction

The steady increase of carbon dioxide (CO\textsubscript{2}) due to anthropogenic emission since the beginning of the industrial era has increased the atmospheric concentration (Boyd et al., 2014). The ocean has a large carbon sink capacity, and increasing atmospheric CO\textsubscript{2} absorbed by the ocean is changing the chemistry of the seawater, causing a decline in pH, termed “ocean acidification” (OA; Boyd et al., 2014). OA has been shown to affect various biological processes of diverse marine species (Doney et al., 2009; Kroeker et al., 2010). For instance, OA can impact the biochemical and elemental composition of organisms (Sato et al., 2003; Torstensson et al., 2013), which can be transferred to higher trophic levels (Rossoll et al., 2012). OA can also drive alterations in the community composition structure of primary producers (Hare et al., 2007; Biswas et al., 2011; Schulz et al., 2013). Strong CO\textsubscript{2} effects may be particularly significant in marine species that experience low natural fluctuations in CO\textsubscript{2} (Riebesell, 2004). In contrast, coastal and brackish-water environments encounter wide and frequent fluctuations in \textit{p}CO\textsubscript{2} (Hinga, 2002; Rossoll et al., 2013) due to large fluxes of organic and inorganic carbon from river run-off (Hinga, 2002), seasonal processes (Melzner et al., 2013) and upwelling of CO\textsubscript{2}-enriched water (Feely et al., 2008), all of which lead to wider pH variation in coastal systems compared to the open ocean (Hinga, 2002). Consequently, it can be expected that coastal
Fatty acids (FAs) are the main components of lipids in cell membranes. In particular, polyunsaturated fatty acids (PUFAs) have important physiological roles in algae, which synthesise them in high amounts. Heterotrophs at higher trophic levels cannot synthesise certain FAs de novo, especially PUFAs, and have to acquire them from dietary sources (Izquierdo et al., 2001). Diverse laboratory studies of monocultures showed that CO₂ alters the FA profile of individual algal species (Sato et al., 2003; Fiorini et al., 2010; Torstensson et al., 2013; Bermúdez et al., 2015). A CO₂-driven change in algal food quality can be detrimental for grazers, as has been shown in a laboratory study under elevated CO₂ levels (Rossoll et al., 2012). A strong decline of PUFAs in a diatom, grown at high CO₂, affected the FA composition of copepods grazing on them and severely impaired their development and egg production rates. Furthermore, increasing seawater CO₂ can modify phytoplankton community composition by favouring certain taxa of primary producers (Graeme et al., 2005). In particular, small-sized cells benefit from high CO₂ (Hare et al., 2007; Biswas et al., 2011; Brussaard et al., 2013). This is ecologically relevant as taxonomic phytoplankton groups have contrasting FA profiles (Galloway and Winder, 2015) and a change in community structure can affect higher trophic levels. For instance, a field study of two cladocerans with different phytoplankton compositions as food sources showed decreased egg production, lipid reserves, body size and abundance when fed with algae from an acidic lake (Locke and Sprules, 2000).

The above observations suggest that changes in planktonic biochemical make-up and associated shifts in community composition of primary producers as a result of OA can affect the transfer of essential compounds to upper trophic levels. Laboratory studies have shown that algae subjected to long-term high CO₂ levels can restore their physiological optima through adaptive evolution (Lohbeck et al., 2012; Bermúdez et al., 2015) and that coastal communities are resilient to OA-driven changes in community composition and biomass (Nielsen et al., 2010; Rossoll et al., 2013). Therefore, it can be expected that organisms in these areas are adapted to high CO₂ fluctuations (Thomsen et al., 2010; Nielsen et al., 2010; Rossoll et al., 2013), hampering any CO₂-driven effects previously observed in plankton communities (Locke and Sprules, 2000; Biswas et al., 2011).

The goal of the present study was to determine whether an increase in CO₂ affects phytoplankton community composition and their FA profile and if any effects are transferred to grazers of a natural plankton community in a coastal/brackish environment. A set of offshore mesocosms, which enclosed a natural plankton assemblage of the Baltic Sea, were used as experimental units. The CO₂ levels ranged from current to projected next century values (Boyd et al., 2014, scenario A2). Algal FAs were measured from total seston and from the copepods Acartia bifilosa and Eurytemora affinis, which were the dominant zooplankton during the experiment (Almén et al., 2016).

2 Material and methods

2.1 Experimental set-up and CO₂ manipulation

Our study was conducted during an offshore CO₂ mesocosm perturbation experiment off the Tvarminne Zoological Station at the entrance to the Gulf of Finland at 59°51.5′ N, 23°15.5′ E during late spring 2012. We used six enclosures with a length of 17 m containing ~55 m³ of natural sea water (Paul et al., 2015). The mesocosms were set up and manipulated as described in detail by Paul et al. (2015) and Riebesell et al. (2013). Carbon dioxide enrichment was achieved in two phases through the addition of CO₂-saturated seawater to four out of six mesocosms. In phase 1, CO₂ was added in five steps between day 1 and day 5 to achieve values from ambient levels (~240 µatm) and a fugacity of carbon dioxide (f(CO₂)) up to ~1650 micro-atmospheres (µatm). In phase 2 on day 15, CO₂ was again added in the upper 7 m to compensate for pronounced outgassing in the CO₂-enriched mesocosms. As described by Paul et al. (2015), dissolved inorganic carbon and total pH (on the total pH scale) were taken every sampling day to determine the carbonate system and determine f(CO₂) in the mesocosms. Samples for nutrients were collected and analysed as described by Paul et al. (2015). Samples for phytoplankton counts were taken every second day and for fatty acid concentrations every fourth day using a depth-integrated water sampler (Hydrosbios, Kiel, Germany), which covered the upper 15 m of the water column. Integrated zooplankton net tows were taken every seventh day as described by Almén et al. (2016).

2.2 Phytoplankton abundance and biomass calculation

Phytoplankton cell counts up to a cell size of 200 µm were carried out from 50 mL water samples, fixed with algaline Lugol’s iodine (1 % final concentration) using the Utermöhl’s (1958) method with an inverted microscope (ZEISS Axivert 100). At 200× magnification, cells larger than 12 µm were counted across half of the chamber area, while smaller cells were counted at 400× magnification on two radial strips. The plankton was identified to genus or species level according to Tomas (1997); Hoppenrath et al. (2009) and Kraberg et al. (2010). Algal biovolume was calculated according to geometric shapes and converted to cellular organic carbon using taxon-specific conversion equations for phytoplankton (Menden-Deuer and Lessard, 2000).
2.3 Fatty acid composition

For analysis of seston fatty acid (FA), 500 mL of seawater was filtered by a 100 µm size pore net and samples were collected in a pre-combusted (450 °C, 6 h) Whatman GF/F (~0.7 µm nominal pore size) filters. For zooplankton, gravid copepod females of *Acartia bifilosa* and *Eurytemora affinis* were picked up with sterile tweezers under two stereomicroscopes (Nikon SMZ800, 25× magnification and Leica 25× magnification) and placed in pre-weighted tin cups. All samples were immediately stored at −80 °C until analysis. FAs were measured by gas chromatography as fatty acid methyl esters (FAMEs) following Breteler et al. (1999). Lipids were extracted overnight from the filters using 3 mL of a solvent mixture (dichloromethane : methanol : chloroform in 1 : 1 : 1 volume ratios). As an internal standard, FAME C19:0 (Restek, Bad Homburg, Germany; c = 20 ng of component per sample) was added, and a C23:0 FA standard (c = 25.1 ng·µL⁻¹) was used as an esterification efficiency control (usually 80–85%). Water-soluble fractions were removed by washing the samples with 2.25 mL of KCl solution (c = 1 mol·L⁻¹), and the remainder dried by addition of NaSO₄. The solvent was evaporated to dryness in a rotary film evaporator (100–150 mbar), redissolved in chloroform and transferred into a glass cocoon. The solvent was evaporated again (10–30 mbar), and esterification was performed overnight using 200 µL 1 % H₂SO₄ (in CH₃OH) and 100 µL toluene at 50 °C. Phases were split using 300 µL 5 % sodium chloride solution, and FAMEs were separated using n-Hexane, transferred into a new cocoon, evaporated and 100 µL (final volume) was added. All solvents used were gas chromatography (GC) grade. FAMEs were analysed using a Thermo GC Ultra gas chromatograph equipped with a non-polar column (RXII-SIL-MS 0.32 µm, 30 m, company Restek) and Flame ionisation detector. The column oven was initially set to 100 and heated to 220 °C at 2 °C·min⁻¹. The carrier gas was helium at a constant flow of 2 mL·min⁻¹. The flame ionisation detector was set to 280 °C, with gas flows of 350, 35 and 30 mL·min⁻¹ for synthetic air, hydrogen and helium respectively. A 1 µL aliquot of the sample was injected. The system was calibrated with a 37-component FAME-mix (Supelco, Germany) and chromatograms were analysed using Chrom-Card-Focus GC software and the fatty acids were clustered according to their degree of saturation: saturated (SFA), monounsaturated (MUFA) and polyunsaturated (PUFA).

2.4 Statistical analyses

The data were analysed with a nested mixed-effects ANOVA model (LME) to determine the differences in taxa biomass (µg·C·mL⁻¹) and relative fatty acid content (%) in the seston and zooplankton) between the CO₂ treatments (µatm of fCO₂), with fCO₂, silicate, inorganic nitrogen (nitrite + nitrate), phosphate, temperature and salinity as fixed effects and sampling day and mesocosm position as nested random variables (random distribution of CO₂ treatments among the mesocosm). Average mesocosm fCO₂ was calculated for the total duration of the sampling period plankton community composition (days 1 to 29) and for FA data analysis (days 1 to 25 for seston FA and days −1 to 33 for zooplankton FA). Linear regression models were used to determine the relation between PUFA and phytoplankton biomass. The similarity in the structure of the plankton community between the treatments was analysed using non-metric multidimensional scaling (NMDS) with Bray distance, auto-transformation and 3 dimensions (k = 3). This analysis distributes the samples in an ordination space according to the biomass of the different taxa in the community along orthogonal principal components using non-Euclidean distances for ordination space, which makes it more robust to the presence of zero values (Clarke, 1993). All statistical analyses were done using the R software environment 3.0.1 (R Development Core Team, 2013).

3 Results

3.1 Plankton community composition

The initial algal community consisted of post-bloom species dominated by small-sized cells, with dinophyta being the most abundant phytoplankton group in all mesocosm throughout the experiment followed by heterokontophyta, euglenophyta, chlorophyta, cyanobacteria bigger than 5 µm (usually filamentous) and small abundances of cryptophyta (Fig. 1). Microzooplankton was present during the entire experimental period, particularly the choanoflagellate *Calliacantha natans* (Fig. 1). The plankton community was analysed from days 1 to 29, which comprised of two phases as described by Paul et al. (2015). In phase 1 (from days 1 to 15), phytoplankton biomass gradually increased until day 10.
Figure 2. The top panels show the mean of the calculated biomass of each plankton taxon in (a) phase 1, between days 0 and 15 and (b) phase 2, between days 15 and 29, in the CO₂ gradient treatments. The bottom panels show the relative biomass of the different plankton groups between (c) phases 1 and (d) phase 2. The x axes show the measured average fCO₂ in each phase, error bars show standard error in (a) and (b) (n = 5 for a; n = 5 for b).

when a bloom started and it reached a peak around day 15 in all treatments, while in phase 2 (from days 17 to 29) the biomass began to decay from around day 19 up to day 29 (Fig. 1).

The more abundant taxa did not show differences in abundance between the CO₂ treatments on both phases (Fig. 2a, b). However, the biomass of some of the less abundant groups was affected by CO₂ within the different phases. In phase 1, the nested mixed effects model analysis of the algal biomass showed that chlorophyta decrease significantly towards high CO₂ levels (Fig. 2a; LME, $F = 7.27$, $p = 0.01$, df = 20). Nevertheless, there was a difference in the relative biomass of the more abundant plankton groups between phases 1 and 2, with a decrease in
3.2 Seston fatty acid composition

The PUFAs represented on average ~26 ± 4, MUFAs ~22 ± 3 and SFAs ~52 ± 4% of the total FA content in the seston over the entire experimental period. The LME analysis of relative PUFA content data showed no significant difference among the CO$_2$ treatments (LME, $F_{45} = 0.0$, $p > 0.05$; Fig. 3a PUFA). Neither did the MUFAs and SFAs show any significant change in abundance in relation with CO$_2$ (LME, $F_{45} = 0.0$, $p = 0.8$ and $F_{45} = 0.06$, $p = 0.79$; Fig. 3a shows MUFAs and SFAs). However, the FA composition of the seston showed that the relative PUFA content significantly decreased over time in all mesocosms (linear regression, $R^2 = 0.52$, $t = -7.64$, $p < 0.0001$, $n = 22$; Fig. 3b shows high CO$_2$ treatments and low CO$_2$ treatments), while the MUFAs and SFAs increased, although the relation of both with time is weak (linear regression, $R^2 = 0.12$, $t = 2.88$, $p = 0.005$ and $R^2 = 0.15$, $t = 3.26$, $p = 0.001$, $n = 22$; Fig. S2). Regarding specific PUFAs, 18:2n6c showed a significant correlation with CO$_2$ and Si, 16:3n4 with CO$_2$, P and Si and 18:3n6 with CO$_2$ and N (Fig. S3).

Nevertheless, PUFAs showed a positive relation with heterokontophyta (linear regression, $R^2 = 0.58$, $p < 0.001$) and dinophyta (linear regression, $R^2 = 0.41$, $p < 0.001$) biomass (Fig. 4a), and with an abundance of silicate (LME, $F = 22.8$, $p < 0.001$, $d.f = 35$) and phosphate (LME, $F = 9.3$, $p < 0.01$, $d.f = 35$) in the mesocosms (Fig. 4b). The PUFAs 18:2n6c and 18:3n3 showed a positive effect of silicate, while 20:5n3c and 22:6n3c showed a significant effect of silicate and phosphate (Fig. S4).

3.3 Copepod fatty acids

The overall PUFA content represented ~12% (311 ± 175 ng FA mg dry wt$^{-1}$) of the total FA of the copepod A. bifilosa and in E. affinis it was ~16% (433 ± 597 ng FA mg dry wt$^{-1}$).

The FAs did not show a CO$_2$-related effect in A. bifilosa (LME, $F = 0.62$, $p = 0.4374$, $d.f = 26$; Fig. 5a) or E. affinis ($F = 0.13$, $p = 0.71$, $d.f = 26$; Fig. 5b). Nevertheless, the relative PUFA content of A. bifilosa and E. affinis showed a significant decrease over time in all high and low CO$_2$ treatments (linear regression, A. bifilosa; $R^2 = 0.22$, $t = -3.288$, $p = 0.002$ E. affinis; $R^2 = 0.47$, $t = -5.51$, $p < 0.0001$, $n = 22$).

Figure 3. (a) Relative polyunsaturated (PUFAs), monounsaturated (MUFAs) and saturated (SFAs) fatty acids content in the seston as a function of $f$CO$_2$ between days 1 and 29. The x axes show the mean $f$CO$_2$ measured during the sampling period, bars show standard error. (b) Relative PUFA composition of the seston showed over time in the 876, 1012 and 1314 µatm $f$CO$_2$ levels (high CO$_2$ treatments) and the 362, 403 and 590 µatm $f$CO$_2$ levels (low CO$_2$ treatments). Horizontal dashed line indicates the position of the overall mean PUFA value.
4 Discussion

4.1 Community composition

The plankton community composition in the present experiment changed over time and showed few differences in relation to the different CO₂ treatments. The observed absence of a strong CO₂ effect on the community composition in the present study is in line with the observations in the western Baltic Sea (Thomsen et al., 2010; Nielsen et al., 2010; Rossoll et al., 2013). In these studies, the authors suggested that the plankton community is adapted to OA due to the current large seasonal and daily variance of pH and CO₂ experienced by the communities in this productive low-salinity region (Thomsen et al., 2010; Nielsen et al., 2010; Rossoll et al., 2013; Almén et al., 2014). Our study region, a coastal zone in the western Gulf of Finland in the northern Baltic Sea, is a brackish environment with low salinity (~5.7 ‰) and has a high fresh water run-off (~ 111 km³ yr⁻¹; Savchuk, 2005) and a strong inter- and intra-seasonal pH variability, sometimes reaching extreme values of 9.2 and 7.4 with an average of 8.1 (Brutemark et al., 2011). Therefore, it seems that the plankton community in our study area, which experiences high natural pH fluctuations, is composed of species and genotypes that are less pH/CO₂ sensitive (Nielsen et al., 2010; Lohbeck et al., 2012; Melzner et al., 2013; Rossoll et al., 2013), which allows them to cope with the CO₂ range applied in the current field experiment.

Chlorophytes were the only group that showed a significant response to the CO₂ treatment, although their contribution to total biomass was low. Chlorophytes decreased at elevated /CO₂, which is in contrast to laboratory studies showing that several species in this group benefit from high CO₂ and can increase their growth rates (Tsuzuki et al., 1990; Yang and Gao, 2003).

4.2 Seston FAs

The relative PUFA content of seston showed a significant decrease over time, which can be attributed to nutrient depletion in the mesocosms, particularly silicate and phosphate concentrations, which caused a decrease in dinophyta and heterokontophyta abundances. These two groups of microalgae have been identified as rich in PUFA content (Galloway and Winder, 2015) and their decrease in the mesocosms explains the concomitant decrease in PUFA. Silicate is required by heterokontophyta for the formation of new frustules during cell division and, when limited, cell division stops (Flynn, 2000). Phosphorus is required for the production of PUFA-rich membrane phospholipids during cell division and growth (Guschina and Harwood, 2009). Nutrient limitation, which causes reduced cell division rates, results in a lower production of phospholipid and increased production of storage lipid, primarily triacylglycerols (Guschina and Harwood, 2009). Triacylglycerols are rich in SFA and MUFA; therefore the increase in triacylglycerols with nutrient limitation typically resulted in decreased proportions of PUFA in most algae (Guschina and Harwood, 2009). This is consistent with our observations in the mesocosms, where the relative PUFA content of seston followed the phosphate concentration. From this perspective, one may expect that any CO₂ effect in algal PUFA will occur when cells are actively growing, since nutrient limitation (silicate and phosphorus) will have more profound consequences in the physiology of the cell than an excess of CO₂.

The absence of a PUFA response to CO₂ is countered by a report of an Arctic plankton community showing an increase
Figure 5. Panels (a) and (b) show the relative polyunsaturated (PUFA), monounsaturated (MUFA) and saturated (SFA) fatty acid content in the copepods *Acartia bifilosa* and *Eurytemora affinis*, respectively, under the $f$CO$_2$ gradient treatments between days 1 and 29. The x axes show the mean $f$CO$_2$ measured during the sampling period, bars shows standard error. (c) Relative PUFA composition of *Acartia bifilosa* (Ac) and *Eurytemora affinis* (Eu) over time in the 876, 1012 and 1314 µatm $f$CO$_2$ levels (high CO$_2$ treatments) and the 362, 403 and 590 µatm $f$CO$_2$ levels (low CO$_2$ treatments). Horizontal dashed line indicates the position of the overall mean PUFA value.

of PUFA at high CO$_2$ levels during part of a mesocosm experiment experiencing nutrient additions (Leu et al., 2013). This was attributed to a change in the plankton community composition due to a rise in abundance of dinoflagellates at high CO$_2$ (Leu et al., 2013). Our results show a decrease in PUFA due to a decline in dinoflagellates. The different PUFA trends between these experiments can be attributed to the specific plankton community composition and their related FA profiles alongside limited phosphate and silicate in our study, which causes a reduction of the biomass of some PUFA-rich taxa. Species composition of a natural plankton assemblage determines its food quality properties as distinct algal taxonomic groups have different FA composition profiles (Galloway and Winder, 2015). A CO$_2$-driven change in the Arctic plankton community composition (Leu et al., 2013) promoted the presence of species rich in PUFA. In our
study the absence of a CO₂ response in taxa composition and the apparent influence of phosphate and silicate limitation in the algal FA composition resulting in a rather homogeneous PUFA concentration between CO₂ treatments.

### 4.3 Copepod fatty acids

Our results showed that the PUFA concentration of the dominating copepod species, *A. bifilosa* and *E. affinis* did not vary between the different CO₂ treatments. However, the PUFAs decrease in both copepods over the experimental period reflects the decline in the PUFA content of the seston. This observation is consistent with other studies showing that copepods strongly rely on their diet as a source of FA and that their composition, especially PUFA, mirrors the algae they graze on (Ishida et al., 1998; Caramujo et al., 2007; Rossoll et al., 2012).

Several studies have shown a limited direct effect on CO₂ in the copepod FA of some species, like the genus *Acartia*, which is rather insensitive to projected high CO₂ exposure up to 5000 µatm CO₂ (Kurihara et al., 2004; Kurihara and Ishimatsu, 2008). Copepods experience widely varying pH conditions on a daily basis during their vertical migration, shown in the same area as the current study (Almén et al., 2014), which may explain their tolerance to pH variations. Several studies have demonstrated that food quality of the available prey in terms of PUFA content can affect egg production, hatching success and nauplii survival in copepods (Jónasdóttir, 1994; Jónasdóttir et al., 2009; Caramujo et al., 2007). Indirect adverse CO₂ effects through the diet of primary consumers have been reported in laboratory and field experiments (Rossoll et al., 2012; Locke and Sprules, 2000). However, the absence of a CO₂-driven change in the community composition of primary producers and the homogeneous algal FA composition due to phosphate and silicate limitations masked any noticeable CO₂-related effects in the algae FA profile which could have affected the copepods during our experiment.

### 5 Conclusions

Considering that the Baltic Sea is a coastal sea with a natural frequent and wide pH variability (Omstedt et al., 2009), it can be expected that the effects of OA on plankton communities will be rather small within the range of predicted values for this century (Havenhand, 2012). A reduced OA sensitivity in systems experiencing high CO₂ fluctuations is supported by our results and other studies using communities from the Baltic (Thomsen et al., 2010; Nielsen et al., 2010; Rossoll et al., 2013). However, in coastal upwelling areas undergoing an increase in hypoxic events, it is likely that elevated CO₂ values presently experienced by coastal organisms and projected by the end of the century (Melzner et al., 2013) will be more recurrent in the future (Feely et al., 2004), with a potential to affect various properties of plankton communities. Nonetheless, it is clear that the plankton community response to OA and concomitant effects on its food quality for higher trophic levels will strongly depend on the sensitivity of primary producers and on how OA affects the species composition of plankton assemblages (Leu et al., 2013; Rossoll et al., 2013). This result is important as any change in primary producers in terms of FA, in particular essential biomolecules such as PUFAs, may scale up in food webs since FAs are incorporated into the lipids of larval fish (Fraser et al., 1989; Izquierdo et al., 2001). Considering that fish is a critical natural resource (FAO, 2010), adverse OA effects on food quality can reach human populations, who rely on fisheries as an important food source (Sargent et al., 1997; Arts et al., 2001).

### 6 Data availability

The phytoplankton biomass and relative fatty acid data can be found in Bermúdez et al. (2016; https://issues.pangaea.de/browse/PDI-13719)

Most other variables from the experiment (e.g. fugacity of carbon dioxide and nutrients) can be found in Paul et al. (2016; doi:10.1594/PANGAEA.863032).

The Supplement related to this article is available online at doi:10.5194/bg-13-6625-2016-supplement.

Acknowledgements. We thank the KOSMOS team and all of the participants in the mesocosm campaign for their support during the experiment. In particular, we would like to thank Andrea Ludwig for co-ordinating the campaign logistics and assistance with CTD operations and the diving team. We also gratefully acknowledge the captain and crew of RV ALKOR (AL394 and AL397) for their work transporting, deploying and recovering the mesocosms and the Tvärminne station and staff for their logistic support. This collaborative project was funded by BMBF projects BIOACID II (FKZ 03F06550) and SOPRAN Phase II (FKZ 03F0611).

The article processing charges for this open-access publication were covered by a Research Centre of the Helmholtz Association.
