Abstract. Coastal upwellings along the eastern margins of major ocean basins represent regions of large ecological and economic importance due to the high biological productivity. The role of these regions for the global carbon cycle makes them essential in addressing climate change. The physical forcing of upwelling processes that favor production in these areas are already being affected by global warming, which will modify the intensity of upwelling and, consequently, the carbon dioxide cycle. Here, we present monthly high-resolution surface experimental data for temperature and partial pressure of carbon dioxide in one of the four most important upwelling regions of the planet, the Mauritanian–Cap Vert upwelling region, from 2005 to 2012. This data set provides direct evidence of seasonal and interannual changes in the physical and biochemical processes. Specifically, we show an upwelling intensification and an increase of 0.6 Tg yr⁻¹ in CO₂ outgassing due to increased wind speed, despite increased primary productivity. This increase in CO₂ outgassing together with the observed decrease in sea surface temperature at the location of the Mauritanian Cap Blanc, 21°N, produced a pH rate decrease of −0.003 ± 0.001 yr⁻¹.

1 Introduction

The excess of CO₂ in the atmosphere, largely responsible for global climate change, has prompted research on the role of the oceans in the carbon cycle. The aim in recent decades has been to assess how the oceans act as sources or sinks within the carbon cycle. To achieve this goal, highly resolved spatial and temporal observations representative of the distribution of CO₂ fluxes between the ocean and atmosphere are necessary. Automated instruments on volunteer observing ships (VOSs) serve to provide as many observations throughout the global ocean as possible. This is in addition to data collected on scientific cruises and at long-term moorings (i.e., Astor et al., 2005; Lüger et al., 2004, 2006; González-Dávila et al., 2005, 2009; Schuster et al., 2009; Schuster et al., 2009; Ullman et al., 2009; Watson et al., 2009; Padin et al., 2010; Gruber et al., 2002; Dore et al., 2003; Santana-Casiano et al., 2007; Bates et al., 2014).

With the amount of data already gathered (http://www.socat.info/; Pfeil et al., 2013), climatologies that present average CO₂ fluxes between the atmosphere and the ocean have been developed, identifying areas acting as a source or sink (Key et al., 2004; Takahashi et al., 2009). However, the low spatial resolution of these databases limits the applicability, especially in coastal areas. Upwelling regions are particularly under-represented in such large databases. Upwelling presents a dynamic process that raises nutrient and CO₂-rich water from relatively deep areas to the surface. The nutrients reaching the photic zone promote primary production, which consumes CO₂. This process generates a CO₂ flux into the ocean. On the other hand, upwelling also brings up CO₂ from deep seawater, which generates uncertainty about the actual role of upwelling areas as a source or sink of CO₂ (Michaels et al., 2001). Indeed, upwelling areas may act as a source or sink of CO₂ depending on their location (Cai et al., 2006; Chen et al., 2013), where upwelling regions at low latitudes mainly act as a source of CO₂ (Feely et al., 2002; Astor et al., 2005; Friederich et al., 2008; Santana-Casiano et al., 2009; González-Dávila et al., 2009) and those at midlatitudes...
mainly act as a sink of CO$_2$ (Frankignoulle and Borges, 2001; Hales et al., 2005; Borges and Frankignoulle, 2002; Borges et al., 2005; Santana-Casiano et al., 2009; González-Dávila et al., 2009). Several anthropogenic interactive effects strongly influence eastern boundary upwelling systems (EBUSs), including upper ocean warming, ocean acidification, and ocean deoxygenation (Gruber, 2011; Feely et al., 2008; Keeling et al., 2010). Moreover, evidence of increasing wind speed that would favor upwelling (Bakun, 1990; Demarcq, 2009; Oerder et al., 2015) supports the possibility of a change in the dynamics of these highly productive areas. Recently, eddy-resolving regional ocean models have shown how upwelling intensification can cause a major impact on the system’s biological productivity and CO$_2$ outgassing (Lachkar and Gruber, 2013; Oerder et al., 2015). Wind observations and re-analysis products are controversial regarding the Bakun intensification hypothesis (Bakun, 1990). Using different wind databases for the Canary region, Barton et al. (2013) concluded that there was no evidence for a general increase in the upwelling intensity off northwest Africa. Marcello et al. (2011) found an intensification of the upwelling system in the same area during a 20-year period, while the alongshore wind stress remained almost stable. Cropper et al. (2014) found that coastal summer wind speed increased, resulting in an increase in upwelling-favorable wind speeds north of 20° N and an increase in downwelling-favorable winds south of 20° N. Santos et al. (2005, 2012) showed that sea surface temperature (SST) was not homogeneous either along latitude or longitude and depended on the upwelling index (UI) intensity. Varela et al. (2015) demonstrated opposite results worldwide depending on the length of data, season evaluated, and selected area within the same wind data set or between data sets. For the Mauritanian region, when wind stress data were used (Varela et al., 2015), a more persistent increasing trend in upwelling-favorable winds north of 21° N and a decreasing trend south of 19° N was determined.

Starting in June 2005, the QUIMA-VOS line visited the Mauritanian–Cap Vert upwelling region northwest of Africa on a monthly basis (Fig. 1 and Table S1 in the Supplement) producing for the first time a high-resolution database of SST and partial pressure of CO$_2$ expressed as fugacity fCO$_2$. This database shows the variations in the CO$_2$ system under changes in the upwelling conditions in the Canary ecosystem from 27 to 10° N for the period 2005 to 2012. More data for the region from other surveys exist (http://www.socat.info/; Pfeil et al., 2013) but they were not considered in this study as they do not follow the same track as the QUIMA-VOS line. Those data are strongly influenced by the distance to the upwelling cells with the corresponding physical effects in the partial pressure of CO$_2$.
temperature was computed from $f\text{CO}_2$ and $A_T$ and with average annual surface ocean total phosphate and total silicate concentrations of 0.5 and 4.8 $\mu$mol kg$^{-1}$, respectively, from the World Ocean Atlas 2009, using the carbonic acid acidity constants by Mehrbach et al. (1973) refitted by Dickson and Millero (1987).

Air–sea $\text{CO}_2$ fluxes ($F\text{CO}_2, \text{mmol m}^{-2} \text{d}^{-1}$) were evaluated as

$$F\text{CO}_2 = 0.24 \cdot k \cdot s \cdot (f\text{CO}_{2w} - f\text{CO}_{2a}^*)$$

(2)

where 0.24 is the scale factor, $k$ is the gas transfer velocity, $s$ is the $\text{CO}_2$ solubility, $f\text{CO}_{2w}$ is the seawater fugacity of $\text{CO}_2$, and $f\text{CO}_{2a}^*$ is the atmospheric fugacity of $\text{CO}_2$. In order to evaluate $(f\text{CO}_{2w} - f\text{CO}_{2a}^*)$, $f\text{CO}_{2a}^*$ data were linearly interpolated to the $f\text{CO}_{2w}^*$ time vector. A positive value for $F\text{CO}_2$ corresponds to $\text{CO}_2$ outgassing from the ocean. $k$ (cm h$^{-1}$) was evaluated with the following parameterization (Nightingale et al., 2000):

$$k = (0.222 \cdot W^2 + 0.333 \cdot w) \cdot (Sc/660)^{-1/2},$$

(3)

where $W$ is the wind speed at 10 m above the sea surface (m s$^{-1}$) and $Sc$ is the Schmidt number.

The variables involved in estimating $F\text{CO}_2$ data (i.e., $f\text{CO}_{2w}$, $f\text{CO}_{2a}^*$, SST, and SSS) were fitted to sinusoidal expressions (Lüger et al., 2004) for a given latitude as follows:

$$X(\text{lat})^* = a_0 + a_1 (t - 2005) + a_2 \sin(2\pi t) + a_3 \cos(2\pi t) + a_4 \sin(4\pi t) + a_5 \cos(4\pi t),$$

(4)

where $a_i$ are the fitting coefficients, $t$ is the sampling time expressed as year fraction, and $X(\text{lat})^*$ represents any of the four fitted variables. This procedure allowed us to reconstruct the series of experimental data for periods without monthly data. The variables were decomposed into an interannual term $X(\text{lat})^*_p = a_0 + a_1 (t - 2005)$ plus a periodic term $X(\text{lat})^*_p = a_2 \sin(2\pi t) + a_3 \cos(2\pi t) + a_4 \sin(4\pi t) + a_5 \cos(4\pi t)$, that is, $X(\text{lat})^* = X(\text{lat})^*_p + X(\text{lat})^*_a$. The periodical term accounts for the high-frequency seasonal variability, while the interannual term marks the year-to-year trend. First, observations were grouped in a natural year for a given latitude, as if they had been taken in a single year (no correction was done for interannual variability). The mean seasonal climatology data associated with the periodic coefficients (i.e., $a_2, a_3, a_4$, and $a_5$) throughout the sampling period were determined. Next, the interannual coefficient $a_1$ was calculated by fitting the residuals resulting from subtracting the periodical component, $X(\text{lat})^*_p$, from the original variable $X(\text{lat})$. By fixing these five coefficients ($a_0$–$a_5$), new distributions for $f\text{CO}_{2w}^*$, $f\text{CO}_{2a}^*$, SST*, and SSS* were constructed with a daily resolution based on the curve fits given for each variable as in Eq. (4), providing the coefficient $a_0$. The accuracy of this fitting procedure was checked by both computing the correlation between experimental and reconstructed values and by determining the mean residuals. The Pearson coefficients were always over 0.87 for
SST (average 0.94 ± 0.03), over 0.69 for both $fCO_2^{sw}$ and $fCO_2^{sw}$ (average of 0.79 ± 0.07 and 0.82 ± 0.04, respectively), and over 0.67 for SSS (average 0.79 ± 0.07). The mean residual on the determination of those four variables were ±3.7 µatm, ±1.5 µatm, ±0.22 °C, and ±0.05 for $fCO_2^{sw}$, $fCO_2^{sw}$, SST, and SSS, respectively. When the monthly satellite SST values were considered, the new SST* function averaged for each month produced values within ±0.47 °C, confirming that this procedure was able to fit non-sampled periods. It was assumed that the same procedure was valid for non-sampled $fCO_2$. Finally, daily $fCO_2^d$ time series between 10 and 27°N with a latitudinal resolution of 0.5° were calculated with a standard error of estimation of 0.5 mmol m$^{-2}$ d$^{-1}$ (15 % of error) that produced mean residuals (experimental $fCO_2^d$–$fCO_2^d$) of 0.4 mmol m$^{-2}$ d$^{-1}$ and Pearson correlation coefficients between experimental and computed $fCO_2^d$ of $r > 0.6$, $p < 0.01$.

Chlorophyll $a$ was calculated from measurements made by the Moderate-resolution Imaging Spectroradiometer (MODIS) aboard NASA’s Aqua satellite. We used monthly averages with a spatial resolution of 9 km supplied by OceanColor Web (http://oceancolor.gsfc.nasa.gov).

Wind data were downloaded from the NCEP CFSR database at http://rda.ucar.edu/pub/cfsr.html developed by NOAA and retrieved from the NOAA National Operational Model Archive and Distribution System and maintained by the NOAA National Climatic Data Center. The spatial resolution is approximately 0.3×0.3° and the temporal resolution is 6 h. The reference height for the wind data is 10 m.

Rainfall data were collected by the precipitation radar installed on the Tropical Rainfall Measuring Mission (TRMM) satellite (http://precip.gsfc.nasa.gov). Monthly averages with a spatial resolution of 0.5×0.5° (product 3A12, version 07) were used (Fig. S1 in the Supplement) in order to explain changes in seasonal surface salinity distributions.

3 Results and discussion

3.1 Physical properties

The variability of the Mauritanian–Cap Vert upwelling was analyzed in terms of the upwelling index (Nykjaer and Van Camp, 1994) (Fig. 2) using satellite wind data. Negative UI values correspond to upwelling-favorable conditions and positive values to downwelling-favorable conditions. The lowest negative values of the index correspond to more intense upwelling. Results clearly distinguish two main subareas in the upwelling system: (1) north of 20°N, the upwelling conditions were favorable throughout the year, although the highest upwellings were observed from March to September with a northward shift from 20 to 22°N. (2) South of 20°N, a marked seasonality was observed with favorable upwelling conditions during autumn and winter, with the maximum intensity observed during January and February. In this region, a downwelling regime is present between May and November when the summer trade winds are replaced by the monsoonal winds advecting warm water (Fig. 3a) northward along the shore (Nykjaer and Van Camp, 1994). Our results (Fig. 2) are quite consistent with previous research (Nykjaer and Van Camp, 1994; Marcello et al., 2011; Santos et al., 2005, 2012; Cropper et al., 2014) but include the years 2010 to 2012, when the UI at around 20–21°N presented a shift of the upwelling intensity from high (∼2000 m$^2$ s$^{-1}$) to strong (∼2800 m$^2$ s$^{-1}$). The analysis of upwelling trends along this route has been controversial since it is highly dependent on the selected region (Santos et al., 2012). The interannual evolution of the UI over the period 2005 to 2012 (Fig. 4, green line) for each degree in latitude indicates an increase in the UI (mean confidence interval of 9 m$^2$ s$^{-1}$) as showed by Santos et al. (2012).

North of 15°N, the upwelling index confirmed the stronger upwelling observed since 1995–1996 in this region after more than a 10-year (from at least 1982 to 1995) period of weaker upwelling (Santos et al., 2012). Local zonal differences between ocean and coastal SST trends determined with satellite data confirmed the intensification of the upwelling regime along the African coast for the period 1982 to 2000 (Santos et al., 2005) and extended by Santos et al. (2012) until 2010 and further extended in this study until 2012 (data not shown). This has been described as a decadal-scale shift of the upwelling regime intensity (Marcello et al., 2011; Santos et al., 2012).

South of 15°N, the annual UI values and trends (Figs. 2 and 4) both for the upwelling (values close to −2800 m$^2$ s$^{-1}$ in January) and downwelling (values reaching 1850 m$^2$ s$^{-1}$ in July) periods are becoming stronger. At 11–12°N, where downwelling is becoming stronger, this results in negative annual temperature rates that approach zero. The UI serves as an indication of decadal variability of the summer monsoon winds and associated northward advection of warm water along the coast (Santos et al., 2012).

The highest upwelling intensity along the VOS line was located at the capes, Cap Blanc and Cap Vert. From satellite chlorophyll $a$ data, especially off Cap Blanc, giant fila-
Figure 3. In situ data of column (a) SST and column (b) SSS in the Mauritanian–Cap Vert coastal region grouped by seasons: winter (W; December, January, and February), spring (Sp; March, April, and May), summer (Sm; June, July, and August), and autumn (Au; September, October, and November). The averaged values for all cruises in Table S1 are shown in black for each season including the 95 % confidence limits. The color code for each cruise is indicated in Table S1.

ments with chlorophyll concentrations above 1 mg m$^{-3}$ persist year-round, spreading from the coast to several hundred kilometers offshore (Fig. 1). North of Cap Blanc the upwelled water originates from the North Atlantic Central Water, and mixes with South Atlantic Central Water (SACW) towards the south (Mittelstaedt, 1983). South of Cap Blanc, the upwelling of nutrient-rich SACW (Mittelstaedt, 1983) promotes phytoplankton growth between Cap Blanc and Cap Vert. Towards 12° N, upwelling is also fed by the North Equatorial Undercurrent (Hagen and Schemainda, 1984). Moreover, the entire northwest African coast is also influenced by the African desert dust transport by the mid-tropospheric Harmattan winds originating from the central Sahara, which supplements the levels of micronutrients (such as iron) to the adjacent marine ecosystem (Mittelstaedt, 1983; Neuer et al., 2004).

The study area is also affected by the migration of the Intertropical Convergence Zone (ITCZ), related to maximum precipitation rates (Hastenrath, 1995). To have a significant satellite precipitation record in our region of interest, precipitation data were integrated longitudinally between 25.25° and 9.75° W. Time series for the latitudinal distribution of integrated precipitation (Fig. S1 in the Supplement) identified the average position of the ITCZ related to maximum precipitation rates. The ITCZ was located at its southernmost position (2° N) during winter, reaching its northernmost position
(14–16° N) around summer. The ITCZ reached our area of interest (> 10° N) from late spring to late summer.

The latitudinal distributions of measured SST and SSS along the vessel track are shown in Fig. 3, grouped by seasons (labeled W, Sp, Sm, and Au). The temperature generally decreased from 10° N to about 20–21° N, where the ship meets the Mauritanian upwelling. From there to the north, the temperature rises as the ship leaves the upwelling area on its way to the Canary Islands. In situ temperature at 27° N shows temperatures in the range of 18 to 24°C with the minimum in winter and maximum in late summer to early autumn. The annual temperature range was somewhat higher at 20° N, with a summer maximum of around 26°C and minimum in spring of about 17°C. At 10° N, temperatures were the highest throughout the year (> 25 °C), with minimum values in winter and maximum in late spring and late autumn. The low values observed during the end of summer are related to the arrival of the ITCZ (Fig. S1 in the Supplement) at those latitudes. The thermal distribution shows a temperature increase as we move to the Equator and a notable cooling at the upwelled waters off Mauritania. The upwelling of cold water from the Cap Vert area was only detected during winter time and the beginning of spring. Salinity minimum values were normally located at 10° N, increasing to maximum values at the Canaries’ latitude. The minimum values of salinity were exceptionally low during autumn from 10 to 16° N by both the freshwater input from rivers that increase their outflow during this season (Nicholson, 1981) and by the northward shift of the ITCZ during this time of the year.

Anomaly fields for temperature and salinity (data not shown) were calculated as the difference between the observations and the mean values at each season for individual latitudes. For temperature, the largest anomalies in winter and spring were located south of 18° N, with values of ±2°C, related to the seasonal cycle of the Cap Vert upwelling. During summer the pattern changed and the largest anomalies were detected in the upwelling area at 18–22° N, with values of ±5°C when the upwelling index for the Mauritanian area was highest (Fig. 2). In autumn the temperature anomalies were shifted slightly to the north, 20–24° N, with values of ±3°C related to the observed pulses in upwelling-favorable winds that affected the surface seawater properties. On the other hand, salinity anomalies showed a very homogeneous pattern in all latitudes for winter, spring, and summer, with values generally within ±0.5. However, during autumn important anomalies south of 18° N were observed, with values in the range of ±1.5. In this region, the upwelling development, the river discharge, and the rainy season controlled the observed distribution (Yoo and Carton, 1990).

To conclude, the data show a permanent annual upwelling regime observed north of 20° N and a seasonal regime across 10–19° N, in accordance with the climatology of previous studies. The data also confirm an increase in upwelling conditions north of 20° N and an increase in downwelling conditions south of 20° N.

### 3.2 Carbon dioxide variability

The latitudinal distribution of the seasonal $f_{\text{CO}_2}^{\text{sw}}$ data (Fig. 5a) showed the highest values between 18 and 23° N for all seasons due to the variability imposed by the upwelling off Mauritania. $f_{\text{CO}_2}^{\text{sw}}$ was consistently greater than the $f_{\text{CO}_2}^{\text{atm}}$. During winter, when the Cap Vert upwelling develops (Fig. 2), the 12–15° N region also presented higher $f_{\text{CO}_2}^{\text{sw}}$ values than those in the atmosphere. $f_{\text{CO}_2}^{\text{sw}}$ data showed a latitudinal shift between the seasons following the shift observed in the upwelling index: in winter, the largest values were located between 19 and 24° N; in spring, they were located between 16 and 22° N; and during summer and autumn, the largest $f_{\text{CO}_2}^{\text{sw}}$ values were recorded in the range 20 to 23° N. The difference between $f_{\text{CO}_2}^{\text{sw}}$ normalized to the mean SST of 22°C for the region (N $f_{\text{CO}_2}^{\text{sw}}$) and $f_{\text{CO}_2}^{\text{sw}}$ (Δ$f_{\text{CO}_2} = N f_{\text{CO}_2}^{\text{sw}} - f_{\text{CO}_2}^{\text{sw}}$, Fig. 5b) reinforced the variability at 20–23° N all year around and at 12–17° N during winter and spring, indicating that upwelling is the major factor contributing to the $f_{\text{CO}_2}$ variability.

According to Takahashi et al. (1993), $f_{\text{CO}_2}^{\text{sw}}$ increases with temperature at a rate of 4.3% µatm°C⁻¹ (between 15 and 26 µatm°C⁻¹ in this area) in a thermodynamically controlled system. At 27° N, as SST increases, the rate was only 7.45 µatm°C⁻¹ due mainly to biological uptake and also to CO₂ outflux. At 20° N the rate became negative with a value

---

**Figure 4.** Latitudinal distribution of the interannual trends for the upwelling index (UI) and for the four experimental variables along the QUIMA-VOS line integrated over every degree between 2005 and 2012. Panel (a) presents the trends for upwelling index (UI, $\times 10^{-3}$ m² s⁻¹, mean confidence interval of 9 m² s⁻¹). SST ($°$C yr⁻¹, confidence interval 0.13°C), and SSS (yr⁻¹, confidence interval 0.06) and (b) the trends for $f_{\text{CO}_2}^{\text{sw}}$ and $f_{\text{CO}_2}^{\text{atm}}$ (confidence intervals 4.23 and 0.44 µatm).
Figure 5. Fugacity of CO$_2$ data in the Mauritanian–Cap Vert coastal region grouped by seasons: winter (W; December, January, and February), spring (Sp; March, April, and May), summer (Sm; June, July, and August), and autumn (Au; September, October, and November). Column (a) $f$ CO$_2$ latitudinal distribution. Column (b), difference between measured and $f$ CO$_2$ values normalized to a constant temperature of 22 °C. The averaged values for all cruises in Table S1 are shown in black for each season including the 95 % confidence limits. The color code for each cruise is indicated in Table S1.

of −10.9 µatm °C$^{-1}$, clearly indicating the important injection of cool and CO$_2$-rich seawater at the upwelling area. The injection is not being compensated for by the solubility nor by the biological carbon pumps. At 10° N, the rate was still negative but only −4.3 µatm °C$^{-1}$ as a result of the seasonal upwelling. $N_f$ CO$_2$ was related with SST (data not shown) in order to account for effects not removed during normalization. At latitudes 19 to 21° N, in the upwelling vicinity of Cap Blanc, an inverse relationship of 70–100 µatm °C$^{-1}$ was found during winter and spring, while in summer and autumn the inverse relationship rate was reduced to 12–18 µatm °C$^{-1}$. While the upwelling indexes at those latitudes were quite constant throughout the year, different rates observed should be related to biological consumption of the CO$_2$ excess. However, during winter and spring the injection of CO$_2$ in the upwelling is not decreased by the biological activity in the area. But during the Chlorophyll $a$ maximum (late spring and summer), most of the CO$_2$ was consumed and/or exported and, therefore, the rate was strongly reduced.
Figure 4 depicts the observed interannual trends ($\alpha_1$ coefficient in Eq. 4) for the four experimentally recorded detrended parameters, together with the UI trend. Confidence intervals of the computed mean annual values for SST, SSS, $f\text{CO}_{2\text{im}}$, and $f\text{CO}_{2\text{sw}}$ were 0.13°C, 0.06, 0.44, and 4.23 µatm, respectively. There was a clear SST trend whereby seawater along the VOS line track was getting cooler with maximum cooling rates at the location of Cap Blanc (21° N) and Cap Vert upwellings (15° N) with rates higher than $-0.2^\circ$C yr$^{-1}$. Data from the first 3 years (2005 to 2008) at 21° N showed lower temperatures with higher cooling rates that reached $-0.7^\circ$C yr$^{-1}$, although 3 years of data are not representative. The area crossed by the VOS line along 17°45’W from 22 to 10° N is located inside the 1000 m isobath that is well inside the mean frontal activity in the Canary region, about 200 km wide (Wang et al., 2015). The different changes in temperature in the coastal slope and offshore waters are related to the different origins of the waters upwelled from depths of about 100 m to the surface (Mittelstaedt, 1983) that spread off the coastal area. The offshore water SST is less variable owing to longer residence time in the ocean surface. These effects and the fact that the VOS line keeps a track line that crossed the upwelling cells at a distance to the coast that varies among cells contribute to the observed spatial variability. There was no attempt to compare latitudinal and longitudinal effects on the observed values. Our experimental data, however, do not show any positive SST rates in the upwelling affected area, and only when the ship approached the Canary Islands did the trends become less negative, reaching a value of $+0.02^\circ$C yr$^{-1}$ at 27° N, similar to those obtained for oceanic Atlantic water (Bates et al., 2014).

$f\text{CO}_{2\text{im}}$ for the area showed the interannual increase of about 2 ± 0.3 µatm yr$^{-1}$ observed in atmospheric stations, while $f\text{CO}_{2\text{sw}}$ presented a heterogeneous distribution. South of 18° N, the rate of increase was always higher than that in the atmosphere reaching a maximum value of 4.1 ± 0.4 µatm yr$^{-1}$ at 10° N. At 27° N, $f\text{CO}_{2\text{sw}}$ increased at a rate of 1.7 ± 0.2 µatm yr$^{-1}$ similar to that determined at the ESTOC time series site (González-Dávila et al., 2010) located at 29°10’N, 15°30’ W. In the Cap Blanc area, $f\text{CO}_{2\text{sw}}$ increased at an average rate of 2.5 ± 0.4 µatm yr$^{-1}$ with the highest values in the period 2005 to 2008 (a rate of 4.6 ± 0.5 µatm yr$^{-1}$ was computed with only those years). Around Cap Blanc, $f\text{CO}_{2\text{sw}}$ always presented lower rates of increase than in the atmosphere with values well below 1 µatm yr$^{-1}$. The observed decrease in SST and the trends in $f\text{CO}_{2\text{sw}}$ can only be explained by a reinforced upwelling. North of 18° N, the lowest rate of increase in $f\text{CO}_{2\text{sw}}$ compared to $f\text{CO}_{2\text{im}}$, together with a decrease in temperature, indicated that upwelling is also favoring an increase in the net community production around the Mauritanian upwelling, consuming and/or exporting the CO$_2$-rich upwelled waters favored by the lateral transport of the Mauritanian current (Lachkar and Gruber, 2013; Varela et al., 2015). The upwelling intensification effects observed in the trends of our experimental data support the recent wind stress trends (Cropper et al., 2014; Varela et al., 2015; Santos et al., 2012) of increased upwelling-favorable winds, at least for the period 2005–2012 in the Canary upwelling region (Figs. 2 and 4). The intensification of the upwelling results in a change in the measured upwelled water properties due to either higher upwelling velocities or deeper source upwelled waters. However, what remains unclear from these records is to what extent those changes reflect upwelling variations due to climate change forcing versus natural decadal variability in the upwelling areas occurring over interannual timescales.

Because the upwelling intensity is changing, other variables will also be affected. pH$_{\text{IT,sw}}$ at 21 ± 0.25° N was computed from $f\text{CO}_2$ and alkalinity pairs of data. Alkalinity was computed from regional correlations with SST and SSS (Lee et al., 2006), which could underrepresent seasonal and interannual variations in upwelling areas. However, pH computed from $f\text{CO}_2$ values are relatively insensitive to errors in $A_T$, and $f\text{CO}_2$ controls the magnitude and variability of pH (a 60 µmol kg$^{-1}$ change in $A_T$ will affect a 0.1 % in pH, that is, about 0.01 pH units). Figure 6 depicts the computed pH$_{\text{IT,sw}}(A_T, f\text{CO}_2)$ data and the harmonic fitting of Eq. (4) providing the seasonal variability and interannual trend. Considering the small systematic biases in interannual dynamics, we determined a decrease in pH at a rate of $-0.003 \pm 0.001$ yr$^{-1}$ (Fig. 6). This decrease is one of the highest rate values determined in several time series stations (Bates et al., 2014), where oceanic SST has only slightly increased in the last decades. However, at the Mauritanian upwelling area and at the location where our VOS line approached this region, SST decreased at a rate of $-0.22 \pm 0.06^\circ$C yr$^{-1}$ (Fig. 4). Solely
this decrease in temperature would increase the pH by a rate of $+0.004 \text{yr}^{-1}$ and the $f CO_2$ would decrease by $4 \mu\text{atm yr}^{-1}$. The net effect of the increase in the amount of rich CO$_2$ and lower pH upwelled waters in the Mauritanian upwelling would be, therefore, a decrease in the pH rate of over $-0.007 \pm 0.002$ units yr$^{-1}$ and an increase in $f CO_2$ of $+6.5 \pm 0.7 \mu\text{atm yr}^{-1}$ (with periods where those rates could reach values of $-0.015 \text{yr}^{-1}$ in pH and $+10.5 \mu\text{atm yr}^{-1}$ in $f CO_2$ as recorded during 2005–2008). Those values are greatly compensated for by the important decrease in the SST resulting in the determined rates of $-0.003 \pm 0.001$ pH units and $+2.5 \pm 0.4 \mu\text{atm}$ of $f CO_2$ per year.

This new data set of experimental values confirmed a decrease in SST and trends in $f CO_2^{sw}$ that can only be explained by reinforced upwelling conditions that favor an increase in the net community production around the Mauritanian upwelling together with a more corrosive environment with pH rates that change by more than $-0.007 \pm 0.002 \text{yr}^{-1}$ at $21^\circ N$. However, the decrease in SST in the upwelling cell buffers this pH rate to values around $-0.003 \pm 0.001 \text{yr}^{-1}$ and $+2.5 \pm 0.4 \mu\text{atm yr}^{-1}$ in $f CO_2$, still among the highest observed in other time series.
3.3 Fluxes of CO₂

The annual air–sea CO₂ flux for the full domain was positive (Fig. 7a), with the area off Cap Blanc with values close to 3.3 mol CO₂ m⁻² (Fig. 7a). North of 24°N, in the area not affected by the coastal upwelling, an average flux of +0.14 ± 0.03 mol CO₂ m⁻² was determined. The ingassing observed during winter and spring of −0.16 ± 0.03 mol CO₂ m⁻² for the full period (Fig. 7) was surpassed by the outgassing during summer and autumn of 0.28 ± 0.14 mol CO₂ m⁻². South of 24°N, it was observed that during spring (Fig. 7d) the photosynthetic activity was not intense enough to uptake the CO₂ injected by the strongest upwelling in the surface waters and thus the area acted as a source of CO₂ with values reaching 1.9 mol CO₂ m⁻² in 2012. During summer (Fig. 7e), primary producers and lateral advection of warm waters by the Mauritanian current could consume and/or export the CO₂-rich waters reaching values of 0.5 mol CO₂ m⁻². During autumn (Fig. 7f), only the area between 20 and 23°N acted as a source of 1–1.5 mol CO₂ m⁻², while the rest was almost in equilibrium. Late autumn–winter upwelling in the 14 to 17°N region contributed to an increased outgassing with a second annual submaximum of about 0.4 mol CO₂ m⁻² in winter (Fig. 7c). South of 14°N, annual CO₂ fluxes decreased from about 0.7 mol CO₂ m⁻² at 14°N to being roughly in equilibrium at 10°N.

The integrated CO₂ fluxes for the area between 10 and 27°N along the VOS line section for the years 2005 to 2012 (Fig. 7b) were between 1.6 and 2.1 × 10⁶ mol of CO₂, with an important annualvariability. FCO₂ increased during the studied period by 0.05 ± 0.02 × 10⁶ mol yr⁻¹. The increase in FCO₂ is related to the observed increase in wind speed (Fig. 4, indicated as UI) north of 16°N. North of 19°N, the influence of wind speed far surpassed the effect of the smaller annual rate of increase in δCO₂ relative to δCO₂ atm, with an exception at 21°N (Fig. 4). South of 16°N, the decrease in wind speed did not exceed the effect of the incremental change in (δCO₂ atm − δCO₂ atm) associated with the increased downwelling indexes (Fig. 4; Santos et al., 2012), resulting in a slightly increasing FCO₂. The variability observed in the annual integrated CO₂ fluxes (Fig. 7b) was related with the basin-scale oscillations, the North Atlantic Oscillation (NAO) index and the east Atlantic pattern (EA) (http://www.cpc.ncep.noaa.gov/data/teledec/telecontents.shtml). Cropper et al. (2014) found winter upwelling variability was strongly correlated with the winter NAO (r values ranged from 0.50 at 12–19°N to 0.59 at 21–26°N), due to the influence of the Azores semi-permanent high-pressure system on the strength of the trade winds. The annual integrated FCO₂ was related with the annual NAO index (Fig. 7b) with a similar r = 0.54, even when fluxes are not only controlled by wind strength. However, Fig. 7a clearly indicates that the Mauritanian upwelling area was the most important contributor to FCO₂ in the study area. The FCO₂ was not significantly correlated with the winter NAO (r = 0.23). Also, the EA index, which represents a southward-shifted NAO-like oscillation, presented a lower significant value (r = 0.48) (trends not shown), in agreement with the upwelling index (Cropper et al., 2014). Overall, the correlation between fluxes and climate indexes describing the main mode of variability across the Atlantic sector may be directly related to the Azores High and its influence on the trade wind strength.

FCO₂ values along the QUIMA-VOS line were used in order to compute a flux budget for the Mauritanian–Cap Vert region. The observed values were assumed to be valid for at least 100 km on both sides of the QUIMA-VOS line. In this case, the total flux of CO₂ being ejected to the atmosphere would reach a value of 16 Tg of carbon dioxide a year for the period 2005–2012, with a rate of increase of +0.6 Tg yr⁻¹. However, it should be considered that the export of the rich δCO₂ upwelled water with high nutrient concentration off the coastal areas would promote a decrease in surface δCO₂ values during productive seasons (as those observed north and south of 21°N) that will result in an ingassing of CO₂. This could balance the observed outgassing increase on a more global scale.

4 Conclusions

The Mauritanian–Cap Vert upwelling area’s sensitivity to climatic forcing on upwelling processes strongly affects the CO₂ surface distribution, ocean acidification rates, and air–sea CO₂ exchange.

The experimental SST and carbon dioxide system variable results for the period 2005 to 2012 confirm upwelling intensification at the Mauritanian–Cap Vert upwelling system. Furthermore, we have shown that upwelling regions at low to midlatitudes are important sources of CO₂ for the atmosphere. As a direct result, the pH is decreasing at a rate of −0.003 ± 0.001 yr⁻¹. Importantly, the amount of emitted CO₂ is increasing annually at a rate of 0.6 Tg due to stronger wind stress, even when primary production seems to also be enhanced in the upwelling area. The monthly record in this EBUS is not yet long enough to determine the extent to which these changes can be attributed to natural decadal variability. These VOS lines must be maintained for years to come and will continue to be one of the most significant contributors to our knowledge of how ocean surface waters are being affected by present and future climate change. The results from VOS lines can provide accurate data for changes in SST, FCO₂, and, consequently, upwelling intensification effects due to global change conditions under decadal natural variability.

Data availability. All data are freely available at the SOCAT database, http://www.socat.info/ (Pfeil et al., 2013), and at the CAR-
The Supplement related to this article is available online at https://doi.org/10.5194/bg-14-3859-2017-supplement.

Author contributions. MGD and JMSC worked in the equipment installation, data collection and designed the study. FM processed the data and generated figures and results. All of them collaborated in the discussion of the data and the writing of the paper.

Competing interests. The authors declare that they have no conflict of interest.

Special issue statement. This article is part of the special issue “The Ocean in a High-CO₂ World IV”. It is a result of the 4th International Symposium on the Ocean in a High-CO₂ World, Hobart, Australia, 3–6 May 2016.
