Abstract. Predicted changes to the precipitation regime in many parts of the world include intensifying the distribution into lower frequency, large magnitude events. The corresponding alterations to the soil moisture regime may affect plant growth and soil respiration, particularly in peatlands, where large stores of organic carbon are due to gross ecosystem productivity (GEP) exceeding ecosystem respiration (ER). This study uses lab monoliths corroborated with field measurements to examine the effect of changing rainfall frequency on peatland moisture controls on CO₂ uptake in an undisturbed cool temperate poor fen. Lab monoliths and field plots containing mosses, sedges, or shrubs received either 2.3, 1, or 0.5 precipitation events per week, with total rainfall held constant. Decreasing rain frequency led to lower near-surface volumetric moisture content (VMC), water table (WT), and soil tension for all vegetation types, with minimal effect on evapotranspiration. The presence of sedges in particular led to soil tensions of ≥ 100 cm of water for a sizeable duration (37 %) of the experiment. Altered rainfall frequencies affected GEP but had little effect on ER; overall, low-frequency rain led to a reduced net CO₂ uptake for all three vegetation types. VMC had a strong control on GEP and net ecosystem exchange (NEE) of the *Sphagnum capillifolium* monoliths, and decreasing rainfall frequency influenced these relationships. Overall, communities dominated by mosses became net sources of CO₂ after 3 days without rain, whereas sedge communities remained net sinks for up to 14 days without rain. The results of this study demonstrate the hydrological controls of peatland CO₂ exchange dynamics influenced by changing precipitation frequency; furthermore, they suggest these predicted changes in frequency will

lead to increased sedge GEP but limit the carbon-sink function of peatlands.

1 Introduction

Northern peatlands cover less than 3 % of the Earth's land surface but have sequestered approximately one-third of the global store of terrestrial carbon (Gorham, 1991; Yu, 2012), serving an important role in the global carbon cycle (Roulet et al., 2007; Limpens et al., 2008). However, this accumulated carbon is expected to be severely affected by climate change due to changes in temperature and precipitation patterns (Kettles and Tarnocai, 1999; Li et al., 2007; Gallego-Sala and Prentice, 2013). The net uptake of carbon in peatlands is due to relatively cool and moist conditions that promote the slower release of CO₂ by ecosystem respiration (ER) than uptake by gross ecosystem productivity (GEP) (Frolking et al., 2002; Rydin and Jeglum, 2006; Frolking et al., 2010). Maintenance of the carbon sink function of peatlands is dependent on a high water table (WT) to minimize respiration (Alm et al., 1999; Strack et al., 2006; Riutta et al., 2007) and high near-surface soil moisture to enable high rates of *Sphagnum* moss photosynthesis (Waddington and Roulet, 2000; Moore et al., 2002; Adkinson and Humphreys, 2011), both of which are controlled by the precipitation regime. Changing climate and weather patterns are leading to an intensification of the precipitation regime (Easterling et al., 2000; Cao and Ma, 2009; Diffenbaugh and Field, 2013), with increasingly longer periods without rain that threaten the sink function of northern peatlands (Nijp et al., 2017).

Climate projections for boreal and temperate regions of the Northern Hemisphere suggest larger but less frequent precipitation events, with limited to no increase in absolute seasonal and annual precipitation (Trenberth, 2011; IPCC, 2013; Sillmann et al., 2013; Wang et al., 2014; Westra et al., 2014). This redistribution of the precipitation regime, especially during the growing season, is expected to lead to decreases in near-surface soil moisture, increased soil moisture variability, and deeper WT (Knapp et al., 2002; Gerten et al., 2008; Vervoort and van der Zee, 2008; Wu et al., 2012). Lower WT levels and near-surface soil moisture due to seasonal drought or temperature-induced increased evapotranspiration (ET) have been shown to lead to reduced net carbon uptake and/or greater rates of CO₂ emission from peatlands (Carroll and Crill, 1997; Alm et al., 1999; Tuittila et al., 2004; Strack et al., 2006; Riutta et al., 2007). Additionally, changes to peatland hydrology through drought have led to changes in vegetation biomass and community composition, which in turn can alter peatland CO₂ exchange depending on the photosynthesis to respiration ratio of the newly established communities (Buttler et al., 2015; Potvin et al., 2015; Churchill et al., 2015; Dieleman et al., 2015). However, these experimental and monitoring studies typically reduce total precipitation input during the study period, while much less research has focussed on the redistribution of rainfall whilst maintaining precipitation totals.

Most studies examining the impact of precipitation frequency on ecosystems have focussed on grassland systems (Hoover et al., 2014; Knapp et al., 2015; Wilcox et al., 2015; Didiano et al., 2016), with comparatively fewer studies in wetland environments. Riparian marsh species' biomass accumulation is negatively affected by month-long periods without added precipitation (Garssen et al., 2014). In peatland systems, shifts in rainfall frequency have been shown to affect net primary production from *Sphagnum* moss (Robroek et al., 2009; Nijp et al., 2014) and methane emission (Radu and Duval, 2018a). *Sphagnum* moss photosynthesis, in particular, responds quickly to trace amounts of precipitation input (Strack and Price, 2009; Adkinson and Humphries, 2011); however, precipitation inputs are only available to these peat-building species for 2–3 days before it is evaporated (Ketcheson and Price, 2014). In the absence of precipitation, *Sphagnum* depends on capillary rise from the saturated zone to the photosynthesizing capitula (Clymo and Hayward, 1982). When WTs are too low, and precipitation is absent, soil water tensions increase and hyaline cells drain, causing desiccation and reduced photosynthesis (Thompson and Waddington, 2008; Strack et al., 2009; McCarter and Price, 2014).

In addition to the non-vascular *Sphagna* species, peatlands can be dominated by shrub and graminoid plant functional types, primarily ericaceous shrubs and sedges, respectively (Rydin and Jeglum, 2006). Vascular plants photosynthesize as long as the component cells retain turgor pressure, and are less susceptible to periods of low precipitation and WT

drawdowns (Malmer et al., 1994; Vile et al., 2011). Peatland shrubs typically have increased productivity when WTs are lowered (Weltzin et al., 2001; Murphy et al., 2009; Bragazza et al., 2013; Munir et al., 2015). Sedges have deep roots (40–100 cm below peat surface) aided by aerenchyma that transport oxygen to lower depths (Silvan et al., 2004); thus, they are tolerant of high WT conditions, but have also been documented to perform well under low WT conditions (Fenner et al., 2007; Dieleman et al., 2015). Additionally, plant and soil respiration rates differ between moss, sedge, and shrub communities (Chimner, 2004; Juszczak et al., 2012; Duval and Radu, 2018). Since vascular plants can comprise a significant portion of peatland productivity and respiration (Szumigalski and Bayley, 1996; Moore et al., 2002; Riutta et al., 2007; Korrensalo et al., 2017), their responses to climate change in concert with *Sphagnum* must be taken into account when assessing peatland carbon cycling.

Previous studies of the effect of lowered water tables on different plant functional types to study the impacts of climate change on peatland carbon cycling have not included the importance of precipitation frequency (Riutta et al., 2007; Churchill et al., 2015; Potvin et al., 2015). Recent research on the interaction between peatland WT position, carbon cycling, and precipitation frequency has focussed on *Sphagnum* moss (Nijp et al., 2014, 2015, 2017). We have recently extended on this research by showing that decreasing rainfall frequency increased vascular plant cover in a cool temperate poor fen in southern Ontario. This consequently led to contracting responses of the seasonal CO₂ balance between community types, with greater flux of CO₂ to the atmosphere from the mosses but greater CO₂ sequestration in sedge and shrub communities (Radu and Duval, 2018b). However, natural variability and logistical constraints in the field prevented us from making a formal assessment of the hydrological controls on the observed differences in NEE. A research gap exists at the intersection of precipitation frequency and its effect on peatland hydrology and CO₂ for a variety of peatland community types. Therefore, the objectives of this study are as follows: (i) to investigate the effect of changing precipitation frequency on peatland hydrology, comprising WT position, VMC, soil water tension, and evapotranspiration (ET), in three common peatland vegetation communities – *Sphagnum* moss only, sedge with *Sphagnum*, and *Sphagnum* with ericaceous shrubs; and (ii) to determine the relationship between hydrologic conditions under the different rainfall frequency treatments and GEP, ER, and net ecosystem CO₂ exchange of those communities. We altered precipitation frequency without changing total precipitation amount in both in situ field plots and lab monoliths through commensurate changes to event magnitudes.

2 Methods

2.1 Study site

The study was carried out on peat monoliths collected from an undisturbed poor fen in southern Ontario, Canada (44°15′13.34″ N, 80°20′46.83″ W). Vegetation was dominated by *Sphagnum* moss (particularly *S. capillifolium* but also *S. rubellum*, *S. fuscum*, and *S. magellanicum*), sedges (*Carex oligosperma* and *Eriophorum vaginatum*), and shrubs (mostly *Chamaedaphne calyculata*, as well as *Rhododendron groenlandicum* and *Vaccinium uliginosum*). Moss ground cover is close to 100 % throughout the site, except in areas with mature shrubs, where ground cover averaged 15 %. Average peat depth in the sample area is 2.1 m overlying a sandy silt till substrate (Burwasser, 1974). The climate near the site is characterized by a mean annual temperature of 6.4 °C and a mean annual precipitation of 996 mm (1981–2010 normal at Ruskview, ON station, data available: http://climate.weather.gc.ca/climate_normals/, last access: 22 June 2018). Rainfall events > 0.2 mm occur on 43 % of the days during the early May – end of September growing season at this climate station. Over the growing season of 2015 at this site we manipulated the rainfall frequency whilst holding total seasonal rain constant; this was undertaken by utilizing rainout shelters over areas dominated by moss, sedge, and shrub communities. We measured plant community changes and CO₂ exchange in response to these manipulated rainfall regimes at this site. Details of this field setup and experiment can be found in Radu and Duval (2018b). Here we focus on the hydrological process controls on the effect of rainfall frequency on CO₂ dynamics through an experiment under controlled laboratory conditions. We also analyzed the field data in the same manner as the laboratory study.

2.2 Experimental setup

Intact peat cores (30 cm diameter × 40 cm height) were collected from the peatland to investigate how precipitation frequency affects CO₂ exchange under controlled climate and WT regimes. Details of core collection and setup can be found in Radu and Duval (2018a). Briefly, cores of each of the three vegetation communities were placed in an environment-controlled chamber (FXC-19 Chamber, BioChambers, Winnipeg, Manitoba, Canada) and water tables were kept at –5 cm for an acclimatization period to the chamber conditions. Climate conditions of the chamber can be found in Table S1 in the Supplement.

We manipulated rainfall frequency over a 4-month study period. Three precipitation frequency treatments were randomly assigned to monoliths of each vegetation community type: 3 events/week (“HiFreq-lab”), 1 event/week (“MedFreq-lab”), and 1 event/2 weeks (“LowFreq-lab”). Simulated rainwater was a diluted Rudolph nutrient solu-

tion (Rudolph et al., 1988; Faubert and Rochefort, 2002) to limit detrimental effects to *Sphagnum* moss growth (Dieleman et al., 2015). The amount of water added for the individual events was adjusted such that the total amount of water was the same between treatments for each 2-week period (see Table S2 for treatment details). At the beginning of the study period, all water levels were set to –5 cm (“high”) and after 2 months were adjusted to –15 cm (“low”). Within each of these two 2-month periods, WT positions were allowed to naturally fluctuate with the addition of rainwater and the loss of water through ET to simulate field conditions.

Perforated PVC wells (1.27 cm diameter) covered with 250 µm Nitex mesh were carefully inserted into peat cores to monitor WT levels; measurements were made three times weekly in all monoliths. VMC was measured with EC-5 soil moisture sensors installed vertically into the peat of each monolith for an integrated depth of 0–5 cm; data were measured at half-hourly intervals with EM50 data loggers. Soil water tension was measured using 15 cm elbow tensiometers (Soil Measurement Systems, Arizona, USA) installed horizontally at 5 cm below moss surface; an INFIELD 7 portable tensiometer (UMS AG, Munich, Germany) was used to measure tension three times per week. Actual evapotranspiration (ET) was measured directly by weighing the monoliths before and after the rainwater additions throughout the study period.

CO₂ exchange was measured three times per week in the environmental chamber as above, although under constant atmospheric conditions (Table S1). CO₂ fluxes were measured using a clear Plexiglas cylindrical chamber (30 cm diameter × 40 cm height). A fan was mounted on the inside of the chamber to mix the air and homogenize the CO₂ concentration during measurements. NEE was measured by fitting the clear chamber to a monolith and sealing it with petroleum jelly to ensure an air-tight seal. The chamber was connected to an infrared gas analyzer (IRGA; EGM-4, PP Systems, Massachusetts, USA). All monoliths were measured sequentially. Following the NEE measurements, ecosystem respiration (ER) was measured with an opaque aluminum cover placed over each chamber to exclude photosynthetically active radiation. Temperatures inside the clear and opaque chambers were monitored during measurements and never found to increase by more than 1.5 °C. Gross ecosystem productivity (GEP) was calculated by subtracting ER from NEE.

2.3 Data analysis

The data were checked for homogeneity and normality with a Levene’s test and a Shapiro–Wilk test, respectively. Differences in hydrological and CO₂ exchange parameters between rainfall frequency treatments and vegetation communities were assessed with linear mixed effects models: WT, VMC, soil tension, ET, GEP, ER, and NPP were response variables; rain fall frequency and water table treatments were fixed effects (with interactions); and the repeated measure-

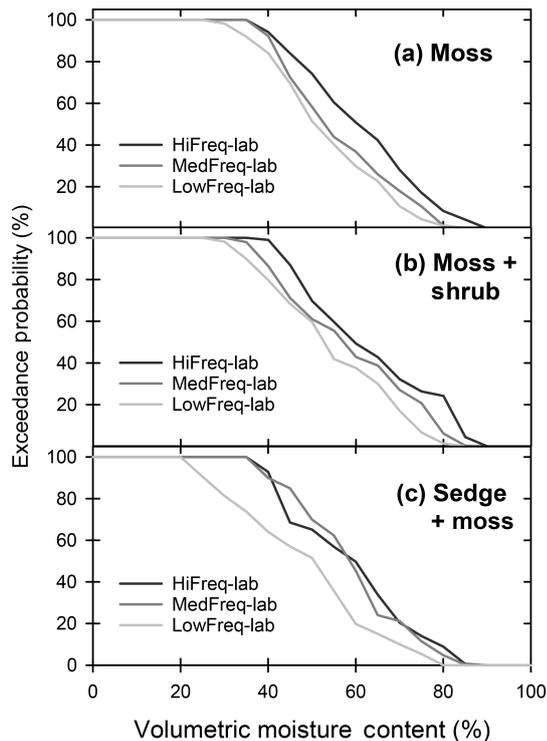

Figure 1. Exceedance probability of VMC from the (a) moss, (b) moss + shrub, and (c) sedge + moss peat monoliths subject to Hi-, Med-, and LowFreq-lab precipitation frequency treatments.

ments of the monoliths were random effect. Relationships between hydrological variables and CO₂ exchange components were examined with linear and nonlinear regression. All statistical analyses were performed using the STATISTICA 8 software package (StatSoft Inc.).

3 Results

3.1 Peatland hydrology under changing rainfall frequency

Decreasing precipitation frequency generally resulted in decreased WT depth, near-surface VMC, and soil tension for all vegetation types, regardless of the initial WT position (Table 1). Water table fluctuation between rainfall treatments for the different vegetation monoliths are shown in the Supplement (Fig. S1). During the high WT period of the experiment, WT depths were significantly lower in the LowFreq-lab relative to the HiFreq-lab treatment in all vegetation communities ($p < 0.001$; Table 1). In the second phase of the experiment when WTs were reset to -15 cm the WT was significantly lower in the LowFreq-lab relative to the HiFreq-lab treatments in the sedge + moss ($p < 0.01$) and moss ($p < 0.05$) monoliths, but not different in the moss + shrub communities.

Near-surface VMC followed the same pattern of WT fluctuation between rainfall treatments throughout the experiment for all vegetation monoliths (Fig. S2). For all vegetation types VMC was $> 60\%$ in the HiFreq-lab monoliths for more than half the experiment (Fig. 1). In comparison, the 50th quantile of VMC in the LowFreq-lab treatment was much lower at 49, 51, and 52 % for the moss (Fig. 1a), moss + shrub (Fig. 1b), and sedge + moss (Fig. 1b), respectively. Overall, VMC was significantly higher in the HiFreq-lab than the LowFreq-lab treatment for the moss and moss + shrub monoliths for both portions of the experiment ($p < 0.001$; Table 1). In the sedge + moss monoliths there were no significant differences in VMC between treatments under the high WT period ($p = 0.298$), but during the low WT period VMC in the LowFreq-lab treatment was significantly lower than either of the more frequent treatments ($p < 0.005$). Similar trends were found during the field experiment (Table S3). There was a significant relationship between VMC and WT for all vegetation communities ($R^2 = 0.77\text{--}0.93$, $p < 0.0001$; Fig. S3), with proportionally greater decreases in VMC for a given WT drawdown for low- versus high-frequency treatments for all vegetation types.

Increasing the duration since the last precipitation event led to significant decreases in VMC for all vegetation communities (Fig. 2). The number of consecutive dry days had a greater effect on VMC declines during the high WT phase of the experiment for both the moss and moss + shrub monoliths. The VMC rate of decline decreased in the moss monoliths by 50 % between the two phases of the experiment, from $1.6\% \text{ d}^{-1}$ during the high WT period ($R^2 = 0.40$; $p < 0.001$) to $0.8\% \text{ d}^{-1}$ ($R^2 = 0.19$; $p < 0.001$) during the low WT phase (Fig. 2a). The decrease in rate of VMC decline was $\sim 31\%$ between high and low WT portions of the experiment for the moss + shrub monoliths (Fig. 2c). In contrast the rate of VMC decline with increasing consecutive dry days increased slightly in the sedge + moss monoliths as the WT was lowered, from $1.6\% \text{ d}^{-1}$ during the high phase ($R^2 = 0.25$; $p < 0.001$) to $1.8\% \text{ d}^{-1}$ during the low WT phase ($R^2 = 0.27$; $p < 0.001$; Fig. 2b).

Average near-surface soil tension increased (became more negative) with decreasing rain frequency in all vegetation treatments (Table 1). These tensions rarely reached -100 cm, the critical level for *Sphagnum* capillary water supply, except in the sedge + moss monoliths subject to the LowFreq-lab treatment during the low WT period, where soil tension frequently was -150 cm. The monoliths experienced linear increases in tension of $\simeq 1.1$, -1.8 , and -1.4 cm d^{-1} of no rainfall under high WT levels for mosses ($R^2 = 0.28$; $p < 0.001$), sedge + moss ($R^2 = 0.22$; $p < 0.001$), and moss + sedge ($R^2 = 0.36$; $p < 0.001$), respectively (Fig. 3). These rates of tension increase generally remained the same in the low WT portion of the experiment for the moss and moss + shrub monoliths (Fig. 3a, c). Conversely, soil tension increased at a rate of -4.3 cm d^{-1} without rain in the

Table 1. Mean (\pm standard deviation) values of volumetric moisture content (VMC), water table (WT), soil matric tension (ψ), and evapotranspiration (ET) for each precipitation, WT, and vegetation community treatment during the laboratory experiment. Different letters indicate significant differences ($p < 0.05$) between precipitation treatments within each water table and vegetation treatment. No letter indicates no significant difference.

sedge + moss monoliths during the low WT phase, more than double the rate under high WT (Fig. 3b).

Sedge + moss evapotranspiration (ET) was significantly higher under HiFreq-lab and LowFreq-lab than MedFreq-lab treatments during both the high- and low WT phases of the lab experiment ($p < 0.05$; Table 1). There were no significant differences in ET in the moss and moss + shrub monoliths. There was also no clear trend between ET and the number of days since rainfall; however, ET exceeded 3.5 mm d⁻¹ for up to 2 days after rainfall in all vegetation communities, and generally remained below 3 mm d⁻¹ for periods up to 14 days without rain.

3.2 CO₂ exchange dynamics

The rainfall frequency treatments had an effect on CO₂ exchange dynamics for all vegetation communities, with low-frequency rain eliciting a response for GEP, ER, and NEE (Table 2). The effect of the high versus low WT treatments was also very strong (Table 2). Figure 4 illustrates this rainfall treatment's effect on CO₂ exchange in greater detail. Gross ecosystem productivity from the moss monoliths decreased with decreasing rainfall frequency under low WT, with rates nearly twice as high in the HiFreq-lab treatment (-0.101 ± 0.010 mg CO₂ m² s⁻¹) compared to the LowFreq-lab treatment (-0.056 ± 0.014 mg CO₂ m² s⁻¹; $p = 0.017$; Fig. 4a). While there were no differences in moss ER between rainfall treatments during high WT, the LowFreq-lab treatment led to significantly more respiration during the low WT period than either

higher-frequency treatments ($p = 0.004$). Moss NEE significantly decreased (less CO₂ uptake/more CO₂ release) with decreasing precipitation frequency in both WT treatments. Under the high WT period, moss monoliths were net CO₂ sinks, with a NEE 3.5 times lower in the LowFreq-lab (-0.010 ± 0.008 mg CO₂ m² s⁻¹) relative to the HiFreq-lab treatment (-0.038 ± 0.006 mg CO₂ m² s⁻¹; $p = 0.013$). During the low WT treatment, the mosses switched to net CO₂ sources, with the LowFreq-lab treatment emitting between three and four times more CO₂ (0.123 ± 0.016 mg CO₂ m² s⁻¹) than the MedFreq-lab (0.040 ± 0.007 mg CO₂ m² s⁻¹) and HiFreq-lab (0.031 ± 0.004 mg CO₂ m² s⁻¹) treatments ($p < 0.001$; Fig. 4a).

The presence of shrubs with the moss increased GEP in the LowFreq-lab treatment during the low WT phase, such that there were no differences in GEP due to rainfall treatment at this time (Fig. 4b). Additionally, during high WT the MedFreq-lab treatment for the moss + shrub monoliths led to more CO₂ uptake than the LowFreq-lab treatment. There were no differences in ER between vegetation treatments for the high WT portion of the experiment for the moss + shrub monoliths, but lower frequency rain led to greater ER than the HiFreq-lab treatment during the low WT portion. The pattern of NEE in response to rainfall frequency for moss + shrub monoliths was similar that observed with moss – under high WT all three treatments were CO₂ sinks, with a shift to sources under low WT (Fig. 4b). While there were no differences in rates of NEE between frequency treatments under high WT ($p = 0.412$), under low WT the

Table 2. Results of the mixed effects models on CO₂ exchange parameters from the monolith experiment. Numerator degrees of freedom for rainfall frequency, water table treatment fixed effects, and their interaction were 2, 1, and 2, respectively, in all models. The denominator degrees of freedom for all models was 222.

MedFreq-lab ($0.042 \pm 0.007 \text{ mg CO}_2 \text{ m}^2 \text{ s}^{-1}$) and LowFreq-lab ($0.07 \pm 0.011 \text{ mg CO}_2 \text{ m}^2 \text{ s}^{-1}$) were nearly 6 and 10 times greater sources of CO₂ than the HiFreq-lab treatment ($0.007 \pm 0.008 \text{ mg CO}_2 \text{ m}^2 \text{ s}^{-1}$; $p = 0.019$), respectively.

There was a trend of greater CO₂ uptake with decreasing rainfall frequency under high WT in the sedge + moss monoliths, with LowFreq-lab resulting in greater GEP ($-0.155 \pm 0.008 \text{ mg CO}_2 \text{ m}^2 \text{ s}^{-1}$) than HiFreq-lab ($-0.098 \pm 0.002 \text{ mg CO}_2 \text{ m}^2 \text{ s}^{-1}$; $p = 0.03$; Fig. 4c). Under low WT, GEP more than doubled in the HiFreq-lab treatment to $-0.214 \pm 0.012 \text{ mg CO}_2 \text{ m}^2 \text{ s}^{-1}$, which was significantly higher than the MedFreq-lab treatment ($-0.146 \pm 0.007 \text{ mg CO}_2 \text{ m}^2 \text{ s}^{-1}$; $p = 0.002$). Under high WT conditions the lower-frequency treatments had higher rates of ER than HiFreq-lab, but this pattern disappeared with lower WT conditions. Overall, under high WT there was no effect of rain frequency on the NEE for the sedge + moss monoliths; however, under low WT there was significantly greater NEE (more carbon uptake) during frequent rain ($-0.045 \pm 0.012 \text{ mg CO}_2 \text{ m}^2 \text{ s}^{-1}$; $p = 0.002$) as compared to MedFreq-lab ($0.008 \pm 0.007 \text{ mg CO}_2 \text{ m}^2 \text{ s}^{-1}$) and LowFreq-lab ($-0.009 \pm 0.012 \text{ mg CO}_2 \text{ m}^2 \text{ s}^{-1}$), both of which were not statistically different from zero (Fig. 4c).

3.3 Controls on CO₂ exchange between rainfall frequency treatments

There were significant unimodal relationships between moss GEP and VMC from the monoliths, and these relationships varied between the rain frequency treatments (Fig. 5a). The relationship was strongest for the high frequency rain treatments, with peak rates of GEP occurring at 65 % VMC. The

strength of the relationship decreased with decreasing rain frequency, as did the VMC at which peak GEP occurred. There were no significant relationships between GEP and WT. The position of the WT was highly correlated with moss ER for all of the rain frequency treatments ($p < 0.001$; Fig. 5b). As rain frequency decreased, WT declines led to proportionally greater rates of ER, with the rate of increase in LowFreq-lab ER being 1.5 times higher than the HiFreq-lab treatment (Fig. 5b). Moss NEE was strongly controlled by near-surface VMC, with significant quadratic correlations for the HiFreq-lab and MedFreq-lab treatments, and a third-order polynomial relationship for the LowFreq-lab rainfall treatment (Fig. 5c). The switch from net CO₂ uptake to a net source occurred in the moss monoliths at VMCs of 60, 62, and 64 % in the HiFreq-lab, MedFreq-lab, and LowFreq-lab, respectively. VMC was below these levels for 49 % of the study in the HiFreq-lab treatment, 66 % in the MedFreq-lab, and 73 % in the LowFreq-lab treatment (Fig. 1). Similar relationships between moss carbon flux and peatland hydrology between rain frequency treatments were found in the field experiment (Fig. S5); however, positive NEE was observed at higher VMC, which occurred for much less of the study period (20 % in the LowFreq treatment).

Under the HiFreq-lab treatment VMC had a unimodal control on rates of GEP from the sedge + moss monoliths, with peak gross production occurring at a VMC of 49 % (Fig. 6a). Decreasing rain frequency rendered this relationship insignificant. Ecosystem respiration was influenced by WT position in the sedge + moss monoliths, with rates increasing between 57 and 71 % faster with WT drawdown in the LowFreq-lab and MedFreq-lab, respectively, than for the HiFreq-lab conditions (Fig. 6b). There were moderate but

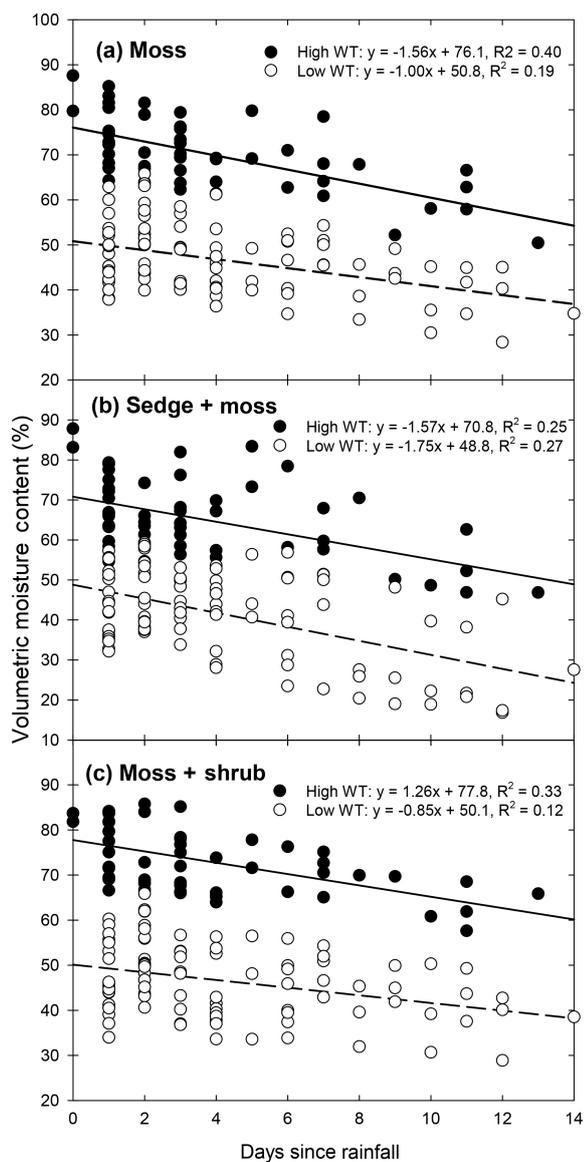

Figure 2. Relationship between daily average VMC and days since the last rainfall/irrigation event for (a) moss, (b) sedge + moss, and (c) moss + shrub monoliths. All regressions were significant ($p < 0.05$).

highly significant ($p < 0.001$) linear correlations between WT and sedge + moss NEE for the lower-frequency treatments, and a quadratic relationship existed between NEE and WT in the HiFreq-lab treatment (Fig. 6c). The trends with the moss + shrub monoliths were similar to the moss-only monoliths (data not shown). There were no significant relationships between WT or VMC with GEP or NEE from the shrub communities in the field, although WT did control ER in these communities ($p < 0.001$).

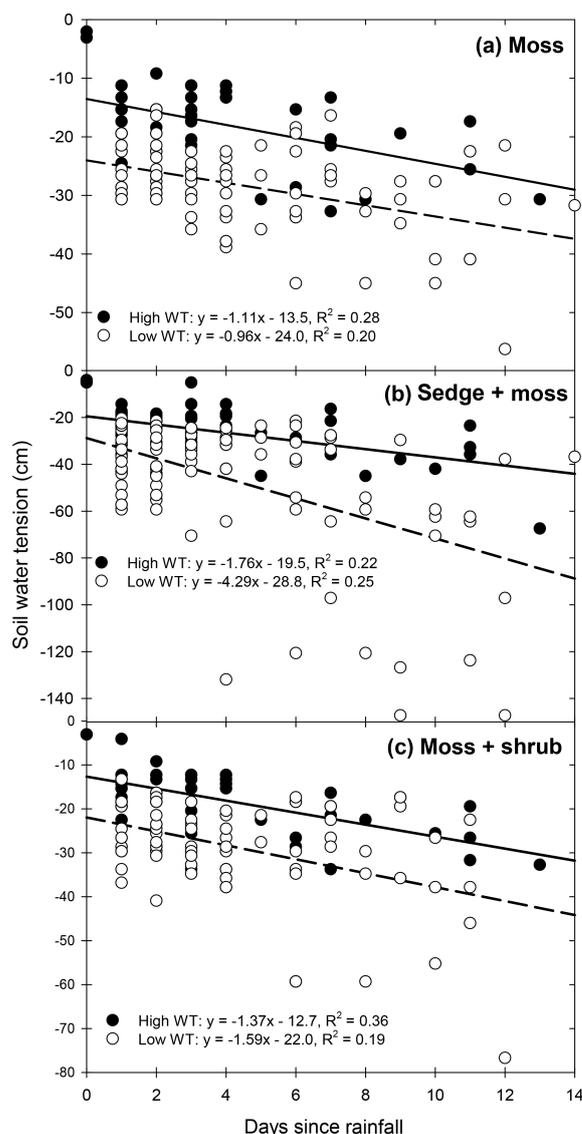

Figure 3. Relationship between daily soil water tension (centimetre of water) and days since the last rainfall/irrigation event for (a) moss, (b) sedge + moss, and (c) moss + shrub monoliths. Data for each vegetation type are separated between high WT and low WT portions of the experiment. Data are combined between precipitation frequency treatments. Linear regressions are provided. All regressions were significant ($p < 0.05$).

Overall, increasing the number of days since the last rainfall event led to a strong increase in NEE (CO₂ efflux to the atmosphere) for the moss monoliths ($R^2 = 0.31, p < 0.01$), a moderate increase for the moss + shrub monoliths ($R^2 = 0.18, p < 0.001$), but almost no increase in the sedge + moss monoliths ($R^2 = 0.05, p = 0.044$; Fig. 7). This relationship was linear for the vascular plant communities, and quadratic for the moss-only monoliths. The moss and moss + shrub monoliths had a net uptake of CO₂ when the duration since the last event was under 3.5 days; however, after

this threshold, there was net emission of CO₂. Conversely, sedge + moss monoliths were largely sinks of CO₂ for up to 2 weeks without rainfall, and were predicted to have a net emission of CO₂ after 15 days between events.

4 Discussion

4.1 Plant community-mediated response of peat hydrology to precipitation frequency

It is expected that a shift in the precipitation to larger, more infrequent events will lead to lower WT levels and drier surface conditions (Knapp et al., 2008; Piao et al., 2009). We found that decreasing the precipitation frequency while holding total seasonal rain constant resulted in lower average WT positions, lower VMC, and higher soil tension in all vegetation communities (Tables 1, S3; Fig. S1, S2). On one hand, the smaller, more frequent precipitation events were able to buffer against seasonal WT declines and maintain more moisture in the near-surface peat layer (Fig. S3). On the other hand, the larger, less frequent events contributed moisture to deeper layers, which led to the observed increased rates of VMC decline with concomitant WT decline (Fig. S3). There-

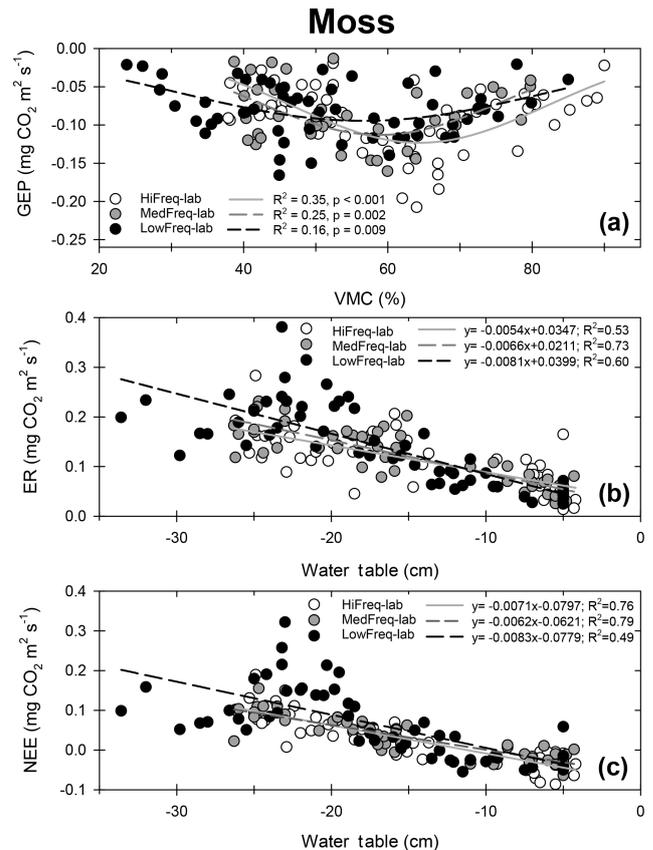

Figure 5. Hydrologic controls on CO₂ exchange in *S. capillifolium*-dominated monoliths, depicting relationships in (a) GEP, (b) ER, and (c) NEE between rainfall frequency treatments. Relationships in (a) are unimodal with indicated correlation coefficients and significance. Relationships in (b) are linear and are indicated with correlation coefficients. All regressions in (b) were statistically significant ($p < 0.001$). Relationships for HiFreq-lab and MedFreq-lab treatments in (c) are second-order polynomial; relationship for LowFreq-lab is third-order polynomial with indicated correlation coefficients and significance.

fore, in addition to climate change leading to increased ET and lower WT positions in peatlands (Whittington and Price, 2006; Munir et al., 2015), the frequency of rainfall events is likely to contribute to even drier surface conditions than is currently considered.

Decreasing rainfall frequency allowed for continued near-surface soil moisture decreases (Fig. 2) and tension increases (Fig. 3). Delivering rain every 3 days, the current average for the studied peatland (Table S2), prevented these large soil moisture declines in communities dominated by *Sphagnum* moss (Table S3; Fig. S2). However, the presence of sedges increased ET relative to the moss-only communities. Vascular plant abundance increases peatland ET, even during periods of limited rainfall (Takagi et al., 1999; Petrone et al., 2004; Admiral and Lafleur, 2007; Wu et al., 2013; Takashi et al., 2016). During the first portion of the experiment when WTs

were high, the rate of drying was the same between moss and sedge + moss monoliths; however, during the low WT portion the rate of drying in the sedge community became 75 % higher than in the moss-only community (Fig. 2a, b). This led to over a four-fold greater rate of tension increase in the presence of sedges (Fig. 3a, b). The low-frequency rain treatment in the sedge + moss community led to near-surface tensions ≤ 100 cm, sometimes after only 4 days without rain. This tension threshold is generally considered the point at which *Sphagnum* can no longer effectively photosynthesize (Price, 1997, Thompson and Waddington, 2008).

In our study -100 cm of tension was reached at a VMC of 37 %, similar to thresholds found in other peatlands (Price and Whitehead, 2004; Cagampan and Waddington, 2008). The high- and medium-frequency treatments for all vegetation communities maintained soil moisture above this value for at least 92 % of the experiment; however, deviations below this threshold increased considerably in the low-frequency rain treatment (Fig. 1). The moss and

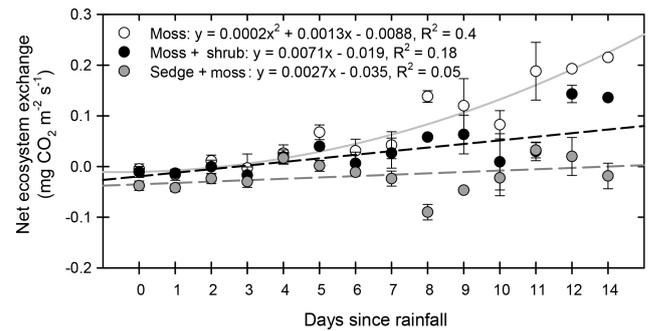

Figure 7. Relationships between NEE and the number of consecutive dry days since rainfall for each vegetation community. Negative NEE represents CO₂ uptake. Error bars represent the standard deviation of the mean. The relationships for the moss and moss + shrub communities are significant at the $p < 0.001$ level; the relationship for the sedge + moss communities is significant at the $p = 0.045$ level.

moss + shrub monoliths subject to low-frequency rain experienced moss-level VMC < 37 % for ~ 10 % of the experiment, whereas the sedge + moss monoliths were below this threshold for 38 % of the experiment. Overall, our results suggest that the interaction between deeper WT and less-frequent precipitation regimes expected with climate change will lead to high tensions that may limit moisture uptake by *Sphagnum* mosses in peatlands dominated by sedges.

4.2 Precipitation frequency – peatland hydrology interactive effects on CO₂ exchange

The precipitation regimes we imposed affected the CO₂ exchange of the vegetation communities. Overall, decreasing rainfall frequency led to decreased NEE (less storage/greater flux to the atmosphere) from the peatland communities tested, with differences in NEE for four of the six vegetation–WT combinations we tested (Fig. 4). Nijp et al. (2014) also found NEE decreased from three *Sphagnum* species as precipitation frequency decreased. Field measurements of CO₂ fluxes from peatlands have also documented decreased GEP and increased ER during extended rainless periods, switching peatlands to net sources of CO₂ during these short periods (Alm et al., 1999; Lund et al., 2012). Seasonal estimates from our study site confirm increased flux of CO₂ to the atmosphere from moss communities during low-frequency rain; however, the abundant shrub communities we were able to test in the field reduced losses to the atmosphere under low-frequency rain, due to higher GEP from the mature shrubs (Radu and Duval, 2018b).

Lower WTs, characteristic of drought periods, can decrease productivity from *Sphagnum*-dominated peatlands through reduced VMC creating a moisture stress (Alm et al., 1999; Chivers et al., 2009; Potvin et al., 2015), as well as increase aerobic respiration through increased oxygen diffusion and a greater depth of aerated soil (Carroll and Crill,

1997; Tuittila et al., 2004); this results in an overall net loss of carbon to the atmosphere. Our study demonstrates that low WT exacerbate the effect of low rain frequency through greater rates of ER, causing the moss and moss + shrub communities to switch from net sinks of CO₂ to net sources (Fig. 4a, b). The combination of low WT and low-frequency rain led to greater rates of near-surface drying (Fig. 2), which would stimulate soil respiration through increased aeration (Silvola et al., 1996). Additionally, low WT resulted in the sedge + moss monoliths, subject to the two lower frequency treatments, switching from sinks to becoming carbon neutral (Fig. 4c). The lack of NEE response to a low WT from the sedge + moss community subject to frequent rain was due to increased GEP, presumably because the high frequency rain maintained moss photosynthesis, while the sedges increased production with lower WT (Wu et al., 2013; Potvin et al., 2015).

Carbon assimilation by *S. capillifolium* was sensitive to rainfall frequency-induced changes in VMC. As rainfall frequency decreased, peak GEP rates were lower and occurred at lower VMC, while the strength of the relationship between GEP and VMC weakened (Fig. 5). Repeated drying and wetting of mosses has been found to result in lower photosynthetic capacity due to damage to moss cellular integrity, including degradation of chlorophyll and rupture of cell membranes (Schippes and Rydin, 1998). The low-frequency rain events allowed for greater near-surface VMC variability, which may have contributed to lower moss GEP at any given VMC. Gerdol et al. (1996) found *Sphagnum* species, including the dominant species in our study, *S. capillifolium*, were unable to resume photosynthesis after an 11-day period without new water. In our study, the mosses continued to photosynthesize, albeit at lower rates, after 13 days without rain, as soil water tensions were weak enough (≥ 100 cm) to allow water uptake. Mosses subject to a regime of 6 days between rainfall events had GEP rates 25 % lower than under a regime of 2 days between events.

The observed increase in the VMC threshold at which the *Sphagnum capillifolium* monoliths switched from NEE sinks to sources as precipitation frequency decreased (Fig. 5a) was related to the concomitant lower WT (Fig. S3a). Therefore, decreasing rain frequency not only lowered near-surface soil moisture but also created an additional stress for the mosses by reducing the availability of capillary water due to the lower WT. During the high WT portion of the experiment VMC was found to drop below these thresholds after 10–11 days without rain; however, the low WT period was characterized by a near-surface VMC almost always less than 60 % (Fig. 2a). Strack et al. (2009) found a sink–source threshold for *S. rubellum* of ~ 45 % VMC in the near-surface peat, and Nijp et al. (2014) found that a VMC of 48 % corresponded to a switch from sink to source for *S. balticum*. All three species are lawn- or small hummock-forming species capable of withstanding low water availability, yet they differ greatly in their response to VMC. The physiological mech-

anisms driving this range in moisture content threshold to NEE among *Sphagnum* species were beyond the scope of our study, but these differences in species-specific responses to soil water content are very important for parameterizing peatland ecosystem models (le Roux et al., 2013; Nijp et al., 2017).

In our study, moss-dominated communities became sources of CO₂ to the atmosphere after less than a week without rain (Fig. 7). This switch from carbon sink to source was primarily driven by decreased VMC between events limiting GEP (Figs. S2, 5a). The monoliths dominated by vascular plants were less affected by rainfall-induced decreases in VMC due to their deeper roots (Silvan et al., 2004), with the sedge communities maintaining uptake or carbon neutrality for the maximum 14 consecutive dry days of our experiment (Fig. 7). In our study region, southern Ontario, seven consecutive dry days occur quite regularly during the growing season, with one or two 14-day dry periods typical within a growing season. The frequency of extreme precipitation events is increasing in the region (Cao and Ma, 2006; Soullis et al., 2016); however, little research has been conducted on the dynamics of the intervening dry periods. Most climate models project these dry periods to increase in both length and recurrence during growing seasons (Orlowsky and Seneviratne, 2012; Sillmann et al., 2013; Walsh et al., 2014).

4.3 Implications for peatland plant functional types and climate change

Our study demonstrates that plant functional types will be differentially affected as rainfall becomes less frequent, particularly if accompanied by lower WT as a result of climate change. *Sphagnum*-only communities experienced a significant decrease in GEP with less frequent rainfall, while GEP in the communities with vascular plants was generally unaffected. Additionally, decreased precipitation frequency had stronger negative implications for *S. capillifolium* in the presence of sedges, with near-surface tensions of ≥ 100 cm after only 3 days without rainfall when the WT was deep (≥ 15 cm). Although we did not measure *S. capillifolium* productivity separate from the sedges in the same communities, white, desiccated *S. capillifolium* capitula were observed in sedge + moss monoliths receiving less frequent rainfall when the water table was low. In a companion study we found that low frequency rain led to significantly more seasonal sedge and ericaceous shrub cover and GEP than high frequency rain (Radu and Duval, 2018b). Ericaceous shrubs in particular seem to thrive, with rates of GEP under LowFreq exceeding HiFreq rates 75 % of the time, generally at multiples of 2–7 under high light conditions (Fig. S4).

Our results show that decreased precipitation frequency will decrease net CO₂ uptake in peatland plant communities dominated by *Sphagnum*, both in the presence and absence of sedges and juvenile shrubs. With the lower water table positions expected as a result of increased ET, we showed

that these communities may switch to CO₂ sources, and decreased precipitation frequency may increase net CO₂ release. Furthermore, increased shrub dominance (Hedwall et al., 2017) is likely to shift the CO₂ balance towards increased CO₂ efflux to the atmosphere. Therefore, we found that decreasing precipitation frequency is likely to lead to a positive feedback for climate change due to increased net CO₂ release to the atmosphere caused by drier surface conditions and a possible shift to sedge- and shrub-dominated communities.

Over the longer term, decreased precipitation frequency is likely to affect the net carbon sink function of temperate peatlands. The reduced NEE of the *Sphagnum*-dominated monoliths with decreasing precipitation frequency (Fig. 4) will progressively limit the storage of carbon in the peat on the annual and decadal scales. We have recently shown that decreased growing season precipitation frequency increases sedge and shrub growth (Radu and Duval, 2018b). The incorporation of vascular plant litter into the peat matrix should increase rates of respiration over and above the short-term results of the present study due to the greater rates of decomposition relative to *Sphagnum* peat (Leifeld et al., 2012; Dieleman et al., 2015; Duval and Radu, 2018). Predicted lower WT position as a consequence of global warming will result in lower long-term rates of carbon accumulation in peatlands (Strack et al., 2006; Peichl et al., 2014; Carlson et al., 2015). Therefore, the combined effects of lowered WTs, increased vascular plant cover, and decreased VMC due to decreased precipitation frequency (Fig. 2) are likely to reduce long-term rates of carbon storage, potentially switching temperate peatlands to carbon sources.

5 Conclusions

Our study has demonstrated that decreasing rainfall frequency results in a lower average VMC, WT, and soil water tension, and increases their variability. In turn, these changes in peat hydrology lead to changes in CO₂ exchange dynamics, with significant effects on GEP and NEE. Moss-dominated communities in particular were strongly affected by changes in rainfall frequency, displaying decreasing gross and net CO₂ uptake with decreasing rain frequency. In contrast, sedge-dominated communities were able to better withstand the longer periods without rain, and actually increased GEP with low-frequency rain when the WT was close to the surface. The empirical relationships between CO₂ exchange and near-surface VMC and WT showed clear differences between rainfall treatments, demonstrating the influence of rain frequency on these couplings. The presence of a low WT was found to have very strong effects on CO₂ exchange, shifting the moss and moss + shrub communities from net CO₂ sinks to net sources while rendering the sedge + moss communities CO₂ neutral under the lower-frequency treatments.

We show the maintenance of near-surface moisture is very important to moss productivity, and as few as four consecu-

tive dry days was sufficient to illicit a net CO₂ efflux response from the moss monoliths. However, the deeper rooting system of the sedges prevented these monoliths from becoming sources for the extent of our experiment (14 consecutive days without rain). Most climate change projections predict increases in the number and recurrence of consecutive dry days during the growing season for many peat-forming areas throughout the globe. Our results suggest this will limit net CO₂ uptake in peatlands. We show that the presence of a lower WT, as predicted due to rising temperatures, increases the effect of lowered precipitation frequency. These rainfall-induced moisture and CO₂ dynamics should be included in peatland ecosystem and climate models.
