Abstract. Earth system scientists working with radiocarbon in organic samples use a stable carbon isotope ($\delta^{13}C$) correction to account for mass-dependent fractionation, but it has not been evaluated for the soil gas environment, wherein both diffusive gas transport and diffusive mixing are important. Using theory and an analytical soil gas transport model, we demonstrate that the conventional correction is inappropriate for interpreting the radioisotopic composition of CO$_2$ from biological production because it does not account for important gas transport mechanisms. Based on theory used to interpret $\delta^{13}C$ of soil production from soil CO$_2$, we propose a new solution for radiocarbon applications in the soil gas environment that fully accounts for both mass-dependent diffusion and mass-independent diffusive mixing.

1 Introduction

Radiocarbon allows us to measure the age of soil-respired CO$_2$ (CO$_2$ diffusing from the soil surface to the atmosphere, also called soil flux as in Cerling et al., 1991), but the traditional reporting convention for radiocarbon was not established for soil gas-phase sampling; rather, it was established for solid (organic matter) sample analysis. The validity of this convention has never been explicitly tested for soil-respired CO$_2$.

The traditional radiocarbon reporting convention, $\Delta^{14}C$ (Stuiver and Polach, 1977), uses a mass-dependent correction based on the isotopic composition of wood. Its purpose is to correct for biochemical fractionation against the radiocarbon isotopologue ($^{14}CO_2$) abundance during photosynthesis, which is assumed to be twice as strong as for $^{13}CO_2$ based on their respective departures in molecular mass from $^{12}CO_2$. The classical reference describing these conventional calculations is Stuiver and Polach (1977).

In the soil gas environment, researchers have different implicit expectations for fractionation processes. They generally assume that $^{14}C$ of CO$_2$ is not biochemically fractionated in the gas phase between the points of CO$_2$ production (biological production of CO$_2$ by soil organisms and roots) and measurement (subsurface or flux chamber samples). This assumption is reasonable based on the short residence time of CO$_2$ (minutes to days) in the soil profile before emission to the atmosphere. However, soil gas isotopic signatures depart in predictable ways from the signature of production because of physical fractionation. It has been recognized for decades that $\delta^{13}C$ of CO$_2$ at any point in the soil profile will never equal the isotopic signature of production because of transport fractionations that alter produced CO$_2$ before it is measured (Cerling et al., 1991). This theory readily extends to $^{14}C$.

We argue here that in the case of soil pore space $^{14}C$ in which mixing of air masses occurs, the assumption that mass-dependent fractionation is twice as large for $^{14}C$ as $\delta^{13}C$ by biochemical and physical processes no longer holds. Using theory and the physical modeling of soil gas transport to illustrate the issue with the current reporting convention correction, we propose an alternative approach for specific use cases.
2 Theory

To understand why the mass-dependent correction used in the Stuiver and Polach (1977) radiocarbon reporting convention may be a poor fit for soil gas studies, we can look at our current understanding of the stable isotopic composition, \( \delta^{13}C \), of soil CO\(_2\) (pore space CO\(_2\), mole fraction with respect to dry air). We use delta notation to present the stable isotopic composition of CO\(_2\):

\[
\delta^{13}C = \left( \frac{R_s}{R_{VPDB}} - 1 \right) 1000, \tag{1}
\]

where \( \delta^{13}C \) is the isotopic composition in per mill (see Table 1 for a full list of abbreviations), \( R_s \) is the \( ^{13}C/^{12}C \) ratio of the sample, and \( R_{VPDB} \) is the \( ^{13}C/^{12}C \) ratio of the international standard, Vienna Pee Dee Belemnite.

From foundational work done by Cerling et al. (1991) we know that the isotopic composition of soil CO\(_2\) is different from that of soil-respired CO\(_2\). Any change in \( \delta^{13}C \) of soil CO\(_2\) with depth is influenced by (1) mixing of atmospheric and biological (or biogeochemical) sources of isotopically distinct CO\(_2\), which may occur via diffusion (no bulk gas flow; referred to as diffusive mixing for the remainder of the paper) or advection (bulk gas flow), and (2) kinetic fractionation by diffusion. The effect of these is illustrated in Fig. 1 using a simulated soil gas profile. In panel (a) two depth profiles of \( \delta^{13}C \) of CO\(_2\) that were modeled in a steady-state environment are shown (the model will be described in Sect. 3). The profiles differ only in soil diffusivity; all other characteristics were held constant, including rates of production, \( \delta^{13}C \) of CO\(_2\) in the atmosphere (\(-8\%e\) circle), and biological production (\(-25\%e\); square with dashed line). In the resultant depth profile with higher soil diffusivity in panel (a), the \( \delta^{13}C \) of soil CO\(_2\) ranges from \(-8\%e\) to \(-15.1\%e\). In the depth profile representing a soil with lower diffusivity, the \( \delta^{13}C \) of soil CO\(_2\) ranges from \(-8\%e\) to \(-20.6\%e\). We stress again that these two isotopic depth profiles differ only due to differences in transport as a result of their varying soil diffusivities. In the depth profile with lower soil diffusivity, atmospheric CO\(_2\) does not penetrate downwards as readily, so the profile shape is much steeper near the soil–atmosphere boundary and is more reflective of the production source composition, \(-25\%e\), at depth. In the depth profile with higher soil diffusivity, atmospheric air of \(-8\%e\) more readily mixes from the surface downward by diffusion, so the near-surface isotopic composition will be more reflective of the atmosphere due to diffusive mixing of these end-members near the soil surface.

Importantly, the soil CO\(_2\) never equals the \( \delta^{13}C \) of production \(-25\%e\) at any depth in either profile in Fig. 1a. It is not possible to directly measure \( \delta^{13}C \) of production in situ because diffusion and diffusive mixing alter the character of CO\(_2\) immediately after its production. From the site of production in the soil, 12CO\(_2\) diffuses somewhat faster through the soil than 13CO\(_2\) because the former has a lower mass. This diffusive difference leads to isotopic fractionation and results in depth profiles of \( \delta^{13}C \) of soil CO\(_2\) that are isotopically enriched (less negative) compared to the source of production. Work by Cerling (1984) and later by Cerling et al. (1991) demonstrated that the mass differences between the two isotopologues led to a difference in the diffusion rate of each in air, amounting to a fractionation of 4.4‰ (note that this applies only to binary diffusion of CO\(_2\) in air and will differ if CO\(_2\) diffuses in other gases). As a result, the \( \delta^{13}C \) of soil CO\(_2\) measured at any depth will be enriched by a minimum of 4.4‰ relative to the biological production CO\(_2\) source. However, the \( \delta^{13}C \) of soil-respired CO\(_2\) can be considerably more enriched than 4.4‰ relative to production due to diffusive mixing with the atmosphere as shown in Fig. 1a.

A convenient theoretical formulation for correcting \( \delta^{13}C \) for both diffusion fractionation and diffusive mixing was introduced by Davidson (1995), following on the work of Cerling (1984) and Cerling et al. (1991). This approach allows one to combine measurements of CO\(_2\) and its isotopic composition within the soil and the air above it to infer the isotopic composition of CO\(_2\) produced in the soil. This only applies when transport within the soil is purely by diffusion (no bulk air movement). The Davidson (Davidson, 1995) solution uses the difference between the diffusion coefficients for \( ^{12}C \) and \( ^{13}C \) as follows:

\[
\delta^{13}_j = \frac{C_a (\delta^{13}_s - 4.4) - C_s (\delta^{13}_s - 4.4)}{1.0044 (C_s - C_a)}, \tag{2}
\]

where \( \delta^{13}_j \) is the \( \delta^{13}C \) composition of CO\(_2\) from soil production (biological respiration within the soil), \( C_s \) and \( \delta^{13}_s \) are the mole fraction and isotopic composition of soil CO\(_2\), and \( C_a \) and \( \delta^{13}_a \) are the mole fraction and isotopic composition of CO\(_2\) in the air just above the soil. In Fig. 2a the mole fraction and isotopic composition of soil CO\(_2\) at a 40 cm depth and of the air just above the soil were “sampled” from model-generated soil depth profiles and the (unrounded) values were used to calculate the isotopic composition of production using Davidson’s equation (\( C_a = 14,780 \) ppm, \( \delta^{13}_a = -20.3832 \%e \), \( C_s = 380 \) ppm, and \( \delta^{13}_s = -8 \%e \)). The resulting \( \delta^{13}_j \) (e.g., Eq. 2) at this depth equals the true isotopic composition of production (see inset box, Fig. 2a). However, because the Davidson approach accounts for diffusion and diffusive mixing, at any given soil depth, not just 40 cm, the modeled values of \( C_s \) and \( \delta^{13}_s \) in Figs. 1a and 2a will always yield (via Eq. 2) the true isotopic composition of production, \( \delta^{13}_j = -25\%e \) (dashed line). If \( \delta^{13}_s \) of soil CO\(_2\) were (erroneously) interpreted to represent the \( \delta^{13}C \) of soil-respired CO\(_2\), the error could be as large as the absolute value of \( (\delta_s - \delta^{13}_s) - 4.4 \%e \). This Davidson (1995) \( \delta^{13}_j \) approach has been shown to be robust when applied to field data from natural soils (Breecker et al., 2012; Bowling et al., 2015; Liang et al., 2016).

While 14C is a radioactive isotope and thus decays with time, the half-life is sufficiently long so that 14CO\(_2\) behaves

Biogeosciences, 16, 3197–3205, 2019

www.biogeosciences.net/16/3197/2019/
similarly to stable isotopes on the timescales at which diffusion occurs in a soil gas system. In this way, \( \delta^{13} \text{C} \) diffusive fractionation theory can be applied to the radiocarbon isotopic composition, \( \delta^{14} \text{C} \), so long as we account for the mass difference. The larger mass of \( ^{14} \text{C} \) means that the diffusion fractionation factor is calculated to be 8.8‰ based on the atomic masses of \( ^{14} \text{CO}_2, ^{12} \text{CO}_2 \), and bulk air (Southon, 2011).

We can show that the \( ^{14} \text{CO}_2 \) distribution in soils will be like that of \( ^{13} \text{CO}_2 \) if we model its distribution through depth in the same synthetic soil gas environment. We can present a modeled soil environment with defined atmospheric conditions for \( \delta^{14} \text{C} \), the \( ^{14} \text{C} \) equivalent to \( \delta^{13} \text{C} \) (Stuiver and Polach, 1977):

\[
\delta^{14} \text{C} = \left( \frac{A_s}{A_{abs}} - 1 \right) \times 1000, \tag{3}
\]

where \( \delta^{14} \text{C} \) is the isotopic composition in per mill, \( A_s \) is the measured activity of the sample, and \( A_{abs} \) is the activity of the oxalic acid standard (both unitless). As in Fig. 1a, in panel (b), the profile with lower soil diffusivity, the downward penetration of atmospheric \( \text{CO}_2 \) into the soil profile is reduced, and as a consequence the isotopic depth profile more closely reflects (but does not equal) the composition of \( \text{CO}_2 \) at a given depth will not equal the isotopic production value of \(-50 \text{‰}\) because of diffusion and diffusive mixing. Similar profiles of \( \delta^{14} \text{C} \) of soil \( \text{CO}_2 \) with depth, highlighting the diffusive effects, have been presented by Wang et al. (1994).

Since \( \delta^{14} \text{C} \) transport of soil \( \text{CO}_2 \) is like that of \( \delta^{13} \text{C} \), it follows that we should apply corrections for \( \delta^{14} \text{C} \) like those in Eq. (2) in order to calculate the isotopic composition of pro-

Figure 1. Modeled steady-state diffusive vertical depth profiles for $\delta^{13}C$ and $\delta^{14}C$ of soil CO$_2$. In panel (a) the $\delta^{13}C$ of atmospheric CO$_2$ (circle) is $-8$‰ and CO$_2$ from biological production (square with dashed line: $\delta_J$) is $-25$‰. In panel (b) the $\delta^{14}C$ of atmospheric CO$_2$ (circle) is 45.5‰ and CO$_2$ from biological production (square with dashed line) is $-50$‰. Both profiles have the same biological production rates and isotopic composition of biological production, but each profile has a different soil diffusivity as indicated.

The $\delta^{14}C$ reformulation of Davidson's $\delta^J$ equation is as follows:

$$\delta^J_{14} = \frac{C_s (\delta^s_{14} - 8.8) - C_a (\delta^a_{14} - 8.8)}{1.0088 (C_s - C_a)},$$

where $\delta^J_{14}$ is the $\delta^{14}C$ composition of soil production, $C_s$ and $\delta^s_{14}$ are the mole fraction and $\delta^{14}C$ composition of the soil CO$_2$, and $C_a$ and $\delta^a_{14}$ are the mole fraction and $\delta^{14}C$ composition of CO$_2$ in the air just above the soil. This Davidson reformulation for $\delta^{14}C$, $\delta^J_{14}$, was applied to a model-generated profile of soil $\delta^{14}C$ at a 40 cm depth in Fig. 2b, like in panel (a) for $\delta^{13}C$ ($C_s = 14780$ ppm, $\delta^s_{13} = -39.3989$‰, $C_a = 380$ ppm, and $\delta^a_{13} = 45.5276$‰; see inset box, Fig. 2b). As was the case for $\delta^{13}C$ in Fig. 2a, the modeled values of $C_s$ and $\delta^s_{14}$ at any depth will yield the true isotopic composition of production, $-50$‰ (dashed line), because this approach accounts for diffusion and diffusive mixing.

The typical approach that has been used for interpreting the $\delta^{14}C$ composition of soil CO$_2$ and soil-respired CO$_2$ (e.g., Trumbore, 2000) differs from the $\delta^{14}C$ example above because a $\delta^{13}C$ correction is applied to account for the mass-dependent isotopic fractionation of biochemical origin, ultimately converting $\delta^{14}C$ to a variant called $\Delta^{14}C$ (Stuiver and Polach, 1977). The derivation of the mass-dependent correction is provided in Stuiver and Robinson (1974), wherein observations are normalized to an arbitrary baseline value of $-25$‰ for $\delta^{13}C$ (a value for terrestrial wood), and the $^{13}C$ fractionation factors are squared to account for the $^{14}C/^{12}C$ fractionation factor as follows:

$$A_{SN} = A_s \left[ \frac{R_s (-25)}{R_s} \right]^2 = A_s \left[ \left( \frac{1 - (25)}{1000} \right) \times R_{VPDB} \right]^2,$$

$$= A_s \left[ \left( \frac{1}{1000} + \delta^{13}C \times R_{VPDB} \right)^2 \right]^2,$$

$$= A_s \left[ \left( \frac{1}{1000} + \delta^{13}C \times R_{VPDB} \right)^2 \right]^2,$$

where $A_{SN}$ is the normalized sample activity, $A_s$ is the sample activity, and $\delta^{13}C$ is the isotopic composition of the sample (soil CO$_2$ in our case). As explained in Stuiver and Robinson (1974), the 0.975 term sometimes used in forms of $A_{SN}$ is equivalent to $\left( \frac{1 - (25)}{1000} \right)$, which we will retain for clarity. The equation for $\Delta^{14}C$, the $\delta^{13}C$-corrected variant of $\delta^{14}C$,
Figure 2. Modeled steady-state diffusive vertical depth profiles for $\delta^{13}C$ (a), $\delta^{14}C$ (b), and $\Delta^{14}C_{\text{old}}$ (c) of soil CO$_2$. The three soil profiles were generated using the same soil production and diffusivity rates (2 $\text{µmol m}^{-3} \text{s}^{-1}$ and $1 \times 10^{-6} \text{m}^{2} \text{s}^{-1}$, respectively). Panels (a) and (b) were prepared using $\delta^{13}C$ and $\delta^{14}C$ as noted. Panel (c) shows an approach consistent with present day, whereby the $\Delta^{14}C$ profile generated by the model incorporates the traditional Stuiver and Polach (1974) correction for biochemical fractionation. Inset “Calculated” panels show how, using input data read directly from each depth profile, a user would arrive at either the correct or incorrect isotopic value of production using a Davidson approach to adjust for in-soil gas transport. The atmospheric source (C$_a$) composition is presented as a white circle, the soil CO$_2$ composition (C$_s$) is a black circle, and the isotopic composition of production is a black square. Note that values for the isotopic composition of soil in the three panels are rounded for ease of reading but are actually $-20.38 \pm 4.4$, $-39.39 \pm 8.8$, and $-48.43 \pm 9.7$, respectively, for panels (a–c). These values are drawn from the curve at a depth of 40 cm.
can then be created from Eq. (5) by substituting in delta notation for \( \Delta^{14}C \) of \( \Delta^{14}C = (A_{SN}/A_{abs} - 1) \times 1000 \) following Stuiver and Robinson (1974):

\[
\Delta^{14}C = \left[ \left( 1 + \frac{\delta^{14}C}{1000} \right) \left( 1 - \frac{25}{1000} \right)^2 - 1 \right] 1000. \tag{6}
\]

Combining Eqs. (3) and (6) leads to

\[
\Delta^{14}C_{old} = \left[ \left( \frac{A_s}{A_{abs}} \right) \left( 1 - \frac{25}{1000} \right)^2 - 1 \right] 1000. \tag{7}
\]

For more information on the derivation of Eqs. (6) and (7) see Stuiver and Robinson (1974), page 88. In Eq. (7) we have added the subscript “old” to highlight that this is the common approach used to date for soil gas applications – we will introduce a “new” model in Eq. (15). The terms on the left-hand side of Eqs. (6) and (7) are identical. Note that \( A_{abs} \) in our notation is equivalent to \( A_O \) in Stuiver and Robinson (1974).

Equation (7) uses \( \delta^{13}C \) as an input parameter to make a mass-dependent correction to obtain \( \Delta^{14}C \), but the profiles of \( \delta^{13}C \) and \( \delta^{14}C \) of soil CO\(_2\) (Fig. 1) highlight the fact that both vary within the soil because of diffusion and diffusive mixing. This makes it unclear what form of \( \delta^{13}C \) should actually be used in the place of the mass-dependent correction in the soil gas environment (\( \delta^{13}C \) of the soil CO\(_2\) is measured but \( \delta^{13}C \) of biological production is not) as diffusive mixing is not a mass-dependent process. When \( \Delta^{14}C_{old} \) is modeled through depth like \( \delta^{13}C \) and \( \delta^{14}C \) in Figs. 1 and 2 it also varies with depth as shown in Fig. 2c. However, using a \( \Delta^{14}C \) variant of Davidson’s \( \delta_2 \) (as for \( \delta^{14}C \) in Fig. 2b) at the same 40 cm depth does not correctly reproduce the specified model value for the \( \Delta^{14}C \) of production of \(-50\%\) like it did for \( \delta^{13}C \) and \( \delta^{14}C \) (\( C_s = 14,780 \) ppm, \( \Delta_s = -48.4319\%\), \( C_a = 380 \) ppm, and \( \Delta_a = 10\%\); see inset box, 2c). We therefore adapted the mass-dependent correction in \( \Delta^{14}C_{old} \) using Davidson’s (1995) theory to demonstrate how and why it should be used for \( \Delta^{14}C \) soil gas applications.

3 Methods – model description

We used an analytical gas transport model to simulate a range of natural soil profiles of \( ^{12}\text{CO}_2 \), \( ^{13}\text{CO}_2 \), and \( ^{14}\text{CO}_2 \) in order to present soil gas transport theory. The model is based on Fick’s second law of diffusion:

\[
\frac{\partial \text{Conc}}{\partial t} = \frac{\partial}{\partial z} \left( D(z,t) \frac{\partial \text{Conc}}{\partial z} \right) + P(z,t), \tag{8}
\]

where \( \theta \) is the soil air-filled pore space, Conc is the concentration, \( t \) is time, \( D(z,t) \) is the soil gas diffusion function, and \( P(z,t) \) is the biological production function, with the latter two dependent on both depth \( z \) and time \( t \).

The model was run in steady state,

\[
\frac{\partial \text{Conc}}{\partial t} = 0, \tag{9}
\]

and both diffusion and production rates were constant with depth:

\[
D(z) = D, \tag{10}
\]

\[
P(z) = P. \tag{11}
\]

The following boundary conditions were used:

\[
\text{Conc}(z = 0) = \text{Conc}_{atm}, \tag{12}
\]

\[
\frac{\partial \text{Conc}}{\partial z}|_{z = L} = 0, \tag{13}
\]

where \( \text{Conc}_{atm} \) is the concentration of CO\(_2\) in air just above the soil and \( L \) is the model lower spatial boundary, the point below which no production or diffusion occurs. Equation (8) is solved analytically to yield the following equation:

\[
\text{Conc}(z) = \frac{P/L}{D} \left( L \times z - \frac{z^2}{2} \right) + \text{Conc}_{atm}. \tag{14}
\]

In the model, isotopologues of CO\(_2\) are treated as independent gases, with their own specific concentration gradients and diffusion rates (Cerling et al., 1991; Risk and Kellman, 2008; Nickerson and Risk, 2009). We assume total CO\(_2\) to be \( ^{12}\text{CO}_2 \) because of its high abundance. The error associated with this assumption is less than 0.01 % (Amundson et al., 1998). Equation (14) is thus applied for \( ^{13}\text{CO}_2 \) and \( ^{14}\text{CO}_2 \).

For the full derivation see Nickerson et al. (2014) Sect. 2.3.

The analytical gas transport model was applied across a range of soil diffusivity (\( 1 \times 10^{-7}, 1 \times 10^{-6}, \) and \( 1 \times 10^{-5} \text{ m}^2 \text{ s}^{-1} \)) and soil production rates (0.5, 1, 2, and 4 \( \mu\text{mol CO}_2 \text{ m}^{-3} \text{ s}^{-1} \)). The specific soil diffusivity and production rates used to generate each profile are stated in the figure caption of that profile. We used a \( \delta^{13}C \) of biological production (\(-25\%\)) and atmospheric \( ^{12}\text{CO}_2 \) (\( \delta_a = -8\%\)) and \( \Delta^{14}C \) of biological production (\(-50\%\)) and atmospheric \( ^{12}\text{CO}_2 \) (\( \Delta_a = 10\%\)) to represent realistic conditions found in nature. The other model boundary conditions were as follows: \( L = 0.8 \text{ m}, z = 0.025 \text{ m}, \) and \( \text{Conc}_{atm} = 15.833 \mu\text{mol m}^{-3} \) (\(~ 380 \text{ ppm} \)). The output of the model under these applied conditions were profiles of \( ^{12}\text{CO}_2 \), \( ^{13}\text{CO}_2 \), and \( ^{14}\text{CO}_2 \) for each depth \( z \) down to the bottom boundary \( L \).

4 Results

4.1 Adapted correction for interpreting radiocarbon values of soil and soil-respired CO\(_2\)

Based on Davidson’s (1995) theory and what we demonstrated with Fig. 2c, rather than using the \( \delta^{13}C \) soil pore space
as a mass-dependent correction, we suggest instead using the value \( \delta_{13} \) (Eq. 2), the biological production of \( \delta_{13} \), in its place in the denominator of Eq. (7) as follows:

\[
\Delta^{14}C_{\text{new}} = \left[ \left( \frac{A_s}{A_{\text{abs}}} \right) \left( 1 - \frac{25}{1000} \right) \frac{1}{\left( 1 + \frac{\delta_{13}}{1000} \right)^2} - 1 \right] 1000. \tag{15}
\]

Values of \( \Delta^{14}C_{\text{new}} \) through depth represent transport-fractionation-corrected soil CO\(_2\) values of radiocarbon, and in comparison to \( \Delta^{14}C_{\text{old}} \), they are corrected for mass-independent diffusive mixing.

A depth profile of \( \Delta^{14}C_{\text{new}} \) is presented in Fig. 3 (dashed line). To generate this soil depth profile we used the numbers from the simulated profiles in Fig. 2 and inserted them into Eq. (2) to determine \( \delta_{13} \) at each depth. These values were then used in Eq. (15) to obtain \( \Delta^{14}C_{\text{new}} \) of soil CO\(_2\) through depth. The \( \Delta^{14}C_{\text{new}} \) profile (dashed line) is more isotopically enriched compared to the \( \Delta^{14}C_{\text{old}} \) profile (solid line) in Fig. 3. Values sampled from the \( \Delta^{14}C_{\text{old}} \) profile (the same as the one presented in Fig. 2c) were not able to reproduce the specified model value for the \( \Delta^{14}C \) of production of \(-50\%_{\text{e}}\) \( \left( C_s = 1780 \text{ ppm}, \Delta_s = -39.3989\%_{\text{e}}, C_a = 380 \text{ ppm}, \right. \) and \( \Delta_a = 45.5276\%_{\text{e}} \) see inset box, Fig. 3).

where \( \Delta^{14}C \) is the \( \Delta^{14}C \) composition of soil production, \( C_s \) and \( \Delta^{14}C_{\text{new}} \) are the mole fraction and \( \Delta^{14}C \) composition of the soil CO\(_2\), and \( C_a \) and \( \Delta^{14}C \) are the mole fraction and \( \Delta^{14}C \) composition of CO\(_2\) in the air just above the soil.

Unlike in the case of \( \Delta^{14}C_{\text{old}} \) demonstrated in the inset box in Fig. 2c, using the same 40 cm depth from the \( \Delta^{14}C_{\text{new}} \) profile, we were able to reproduce the specified model value for the \( \Delta^{14}C \) of production of \(-50\%_{\text{e}}\) \( \left( C_s = 1780 \text{ ppm}, \Delta_s = -39.3989\%_{\text{e}}, C_a = 380 \text{ ppm}, \right. \) and \( \Delta_a = 45.5276\%_{\text{e}} \).

### 4.2 Work-arounds and establishing new best practice

In the soil gas environment, \( \Delta^{14}C_{\text{new}} \) convention should be used to properly interpret soil-respired CO\(_2\) from soil CO\(_2\), as it corrects for all related transport fractionations. For researchers who have soil CO\(_2\) data previously interpreted using \( \Delta^{14}C_{\text{old}} \), the following steps will help correct for transport fractionations: (1) use \( \delta_{13} \) and \( \Delta^{14}C_{\text{old}} \) to back out the activity of the sample \( A_s \); (2) calculate the isotopic composition of production for \( \delta_{13} \) using Eq. (2), \( \delta_{13}^{13} \); (3) use \( \delta_{13} \) and \( A_s \) in Eq. (7) to calculate \( \Delta^{14}C_{\text{new}} \), and finally (4) determine the radiocarbon isotopic composition of production using Eq. (16), \( \Delta^{14}J \).

Going forward, several changes to best practice are recommended. On a lab level, for new soil CO\(_2\) data, we propose that laboratories report radiocarbon using Eq. (3) for \( \delta^{13}C \), the uncorrected radiocarbon variant, so that the first step above (use \( \delta_{13} \) and \( \Delta^{14}C_{\text{old}} \) to back out the activity of the sample: \( A_s \)) can be avoided, and researchers can proceed with steps 2–4. We also suggest that researchers measure \( \delta^{13}C \).
alongside $\Delta^{14}C$ so that they are not dependent on the AMS-measured $\delta^{13}C$ for potential back corrections.

The Davidson (1995) $\delta J$ method was the gradient approach we used in our study, but alternative gradient approaches, such as those presented for $\delta^{13}C$ by Goffin et al. (2014) and Nickerson et al. (2014) and for $\Delta^{14}C$ by Phillips et al. (2013), would likely be similarly successful in producing depth-dependent compositions of production. They are, however, not quite as straightforward as the $\delta J$ method.

5 Conclusions

This traditional $\Delta^{14}C$ solution, which uses $\delta^{13}C$ of soil CO$_2$ as a mass-dependent correction, is not appropriate for the soil gas environment, as it does not account for mass-independent mixing processes. We propose a new best practice for $\Delta^{14}C$ work in the soil gas environment that accounts for gas transport fractionations and produces true estimates of $\Delta^{14}C$ of production.

Data availability. No data sets were used in this article.

Author contributions. JEE, DRB, and DAR conceptualized the theory and method for proving the new solution for radiocarbon applications in the soil gas environment. JEE carried out the modeling, validation, visualization, and writing of the original draft. DRB, DAR, and JEE reviewed and edited the draft.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. Thanks to Thure Cerling for helpful discussions on the paper and to anonymous reviewers whose input was important in shaping the final presentation of this material.

Financial support. Jocelyn E. Egan is grateful for support from a Research-in-Residence Award from the Inter-University Training in Continental-scale Ecology Project, National Science Foundation, Directorate for Biological Sciences (grant no. EF-1137336). Jocelyn E. Egan was also funded by the Natural Sciences and Engineering Research Council of Canada (NSERC). This research was also supported by the US Department of Energy, Office of Science (grant no. DE-SC0010625).

Review statement. This paper was edited by Dan Yakir and reviewed by three anonymous referees.
